The Mechanism of Intrusion of the Inyo Dike, Long Valley Caldera, California

ZE'EV RECHES

Geology Department, Hebrew University, Jerusalem, Israel

JONATHAN FINK

Geology Department, Arizona State University, Tempe

We analyze the intrusion of the 11-km-long Inyo Dike at the margins of Long Valley caldera, eastern California. The dike trends N07°W and is divided into at least three segments which are rotated by as much as 25° with respect to the main trend. The dike seems affected primarily by the regional stress field of right-lateral shear of the western United States and by the local thermal conditions of the crust; the dike seems unaffected by the preexisting caldera margins and Sierra-Nevada frontal fault system. The high heat flow in Long Valley caldera implies that crustal rocks below 3-4.5 km deform by steady state creep under tectonic strain rate and support low to vanishing tectonic shear stresses. The upper rocks, above 3-4.5 km, deform by frictional slip along fractures and may support tectonic shear stresses as high as 24 MPa. We demonstrate that depth variations of tectonic stresses may have a profound effect on the segmentation and rotation of dikes, both at Long Valley and in other areas of high heat flow. The analysis places constraints on several tectonic conditions. The Inyo Dike intruded under a tectonic stress state with a horizontal maximum compression oriented N07°W. The maximum extensional fracture strength of the host rocks is 1-2.5 MPa, and the pressure drop within the propagating Inyo Dike was about 0.55 MPa/km. The volatile overpressure in the magma chamber was about 15 MPa during eruption of rhyolitic lavas at the Inyo Domes.

INTRODUCTION

Seismic activity and ground deformation since 1980 have focused attention on Long Valley caldera as a site of incipient volcanic activity. The last major volcanic event to occur in this area was the emplacement of the Inyo Domes and associated pyroclastic deposits approximately 550 years ago; these features were fed by an 11-km-long dike we will refer to as the Inyo Dike. The distribution of Holocene vents in Long Valley suggests that future eruptions will likely be fed by pipes situated along dikes.

The Inyo Dike provides a good opportunity to analyze the process of magma propagation from source area to the surface, thanks to detailed studies of the region. The three-dimensional geometry of the dike has been resolved on the basis of surface structural features and mapping of the domes [Fink and Pollard, 1983; Fink, 1985; Mastin and Pollard, in press]. Three research drill holes at the Inyo Domes provide subsurface control on the dike geometry and its composition [Eichelberger *et al.*, 1985]. The vast body of geophysical measurements in Long Valley caldera further constrains the mechanical and rheological conditions of the upper crustal rocks here [e.g., Hill *et al.*, 1985].

In this paper we explain the dike geometry in terms of the interaction between tectonic stresses and local variations in host rock rheology. We evaluate relationships between tectonic and magmatic stresses and estimate the magnitude of magmatic pressure at depth necessary to get the dike to the surface. Application of the model to other volcanoes is also discussed.

THE INYO VOLCANIC CHAIN

Based on mapping and age dating of pyroclastic deposits and silicic extrusions in the western part of Long Valley caldera, Miller [1985] proposed that the three largest Inyo Domes and the adjacent

Inyo Craters were fed by a single 11-km-long, north trending dike (Figure 1). Fink [1985] mapped ground cracks, normal faults, and phreatic pits on and around the domes and concluded that they were fed by a N-S trending dike that divided into at least three NNE trending segments as it approached the surface from the south (Figure 2). He further suggested that rotation of the segments increased upward and that the top of each segment sloped upward to the north.

Major tectonic features around the Inyo Domes include the roughly ellipsoidal caldera-bounding faults and the N30W trending fault system of the Sierra Nevada block (Figure 1a). The immediate vicinity of the Inyo Domes contains normal faults and vertical fractures trending mostly N15°W to N20°E (Figure 1b) [Benioff and Gutenberg, 1939; Bailey *et al.*, 1976; Miller, 1985; Fink, 1985; Mastin and Pollard, in press]. The trends of the Inyo area are apparent also in detail. For example, a 300-m-long fissure, known as Earthquake Fault, is found 6 km south of the Inyo Craters along the Inyo trend (Figure 1b); it is composed of many 2- to 20-m-long segments whose trends alternate within the same range of N15°W to N20°E (Figure 3).

The presence of the Inyo Dike was confirmed by the third drill hole of the Inyo Scientific Drilling Program [Eichelberger *et al.*, 1985]. This slanted hole was sited between Obsidian Dome and South Glass Creek Dome (Figure 1b) where at a vertical depth of 620 m, the hole intercepted a 7-m-wide rhyolite dike. The dike was surrounded by a 30-m-wide zone of fractures, some of which were filled with intrusive pyroclastic material. This dike did not vent to the surface at the drill hole area but fed the 35-m-wide conduit of Obsidian Dome, about 1 km north of the drill hole. The point of intersection was west of a line connecting the vent areas of the two domes, suggesting 10° of clockwise rotation at this depth. The direction of this rotation was the same but the magnitude was less than the 25° indicated by surface mapping [Fink, 1985].

The source for the Inyo lavas has been located at the northern end of the chain according to chemical considerations [Bailey *et al.*, 1983], at its southern portion based on structural analysis [Fink,

Fig. 1a. Simplified geologic map of Long Valley caldera and surrounding area, showing the distribution of post Bishop Tuff volcanic rocks, the Inyo/Mono volcanic system, major faults, and three earthquake epicenters mentioned in the text [after Hill *et al.*, 1985].

1985] or at several separate magma chambers along the chain [Sampson and Cameron, 1987]. While the Long Valley caldera is underlain by a large and shallow magma chamber, several geophysical techniques "... suggest a much smaller, less well defined dike-like chamber 10-20 km beneath the Mono [-Inyo] Craters chain" [Hill *et al.*, 1985].

Geophysical data from the Inyo area have been collected as part of geothermal exploration, in conjunction with the Inyo Drilling Program, and in order to monitor the potential for future eruptions. Investigations concerning heat flow [Sorey, 1985; Blackwell, 1985], ground deformation [Savage and Cockerham, 1984], and seismic activity [Julian and Sipkin, 1985] are most important for the model developed below.

EMPLACEMENT OF THE INYO DIKE

An intruding dike may be envisioned as an internally pressurized fracture which propagates in the crust due to its dilation by molten magma. The dike extends when the forces which support its intrusion exceed the forces which resist the intrusion, and the dike stops under the opposite conditions. In the present section we evaluate the balance between these forces for the Inyo Dike.

The dike intrusion is supported by the following.

1. P_h , the hydrostatic pressure of the intruding magma which originates from the density difference between the molten magma and the solid rock.

2. P_v , the overpressure in the magma chamber from which the dike propagates. The most likely source for this overpressure is the undissolved volatiles in the magma [Blake, 1984].

3. The deviatoric tectonic stress normal to the dike, σ_t .

The dike intrusion is resisted by the following.

4. P_f , the fracture strength of the host rocks in the crust which has to be overcome.

5. P_{vis} , the pressure drop in the magma due to viscous resistance to flow of the magma.

6. P_e , the elastic resistance of the host rock to the intruding and dilating dike.

We define the sum of these stresses and pressures as the driving pressure (P_d) of the dike. At depth z below the surface the driving pressure is

$$[P_d]_z = P_h + \sigma_t - P_{vis} + P_v - P_f - P_e \quad (1a)$$

Positive driving pressure indicates a propagating dike, whereas a vanishing driving pressure indicates a dike that stopped. Compressive stresses are positive.

When the dike intrudes into a uniform host rock, three of the terms on the right side of (1a), P_v , P_f and P_e , do not vary significantly with depth, and we rewrite (1a) as

$$[P_d]_z = P_{con} + [P_h + \sigma_t - P_{vis}]_z \quad (1b)$$

where $P_{con} = P_v - P_f - P_e$ is a constant for a given dike configuration.

Several investigators have designated the driving pressure as

$$P_d = (P_m - \sigma_t)$$

where P_m is defined as the magma pressure in the dike [e.g. Pollard and Muller, 1976; Delaney *et al.*, 1986]. From (1a) the magma pressure of previous studies is

$$P_m = [P_h - P_{vis}]_z + P_v - P_f - P_e \quad (1c)$$

We demonstrate below that the six components of the driving pressure, including the five components of the magma pressure (equation (1c)), may be separately calculated for the Inyo Dike.

We first calculate the hydrostatic pressure, P_h , from the geometry of the dike, and the tectonic stress, σ_t , from the dike orientation and local crustal rheology. Then, the sum of constant pressures, P_{con} , and the viscous resistance, P_{vis} , are calculated from observations on the depth of the Inyo Dike. Finally, the magnitudes of the elastic resistance, P_e , and fracture strength, P_f , are derived from dike geometry.

DEPTH-DEPENDENT PRESSURES

Hydrostatic Pressure, P_h

Consider the hydrostatic pressure on a dike which propagates from a magma chamber at depth H to depth z ; mean crustal density is ρ , and magma density is ρ_m . The lithostatic pressure due to the crustal rocks is ($\rho g H$) on the magma chamber and ($\rho g z$) at the tip of the dike. The hydrostatic pressure in the molten magma within the dike decreases from the lithostatic pressure ($\rho g H$) at the chamber depth, by [$\rho_m g (H - z)$] at depth z below the surface (Figure 2b). Thus the hydrostatic pressure in the magma at depth z is the difference,

$$(\rho g H) - [\rho_m g (H - z)]$$

From this hydrostatic pressure we subtract the lithostatic pressure at depth z and obtain the deviatoric hydrostatic pressure of the magma,

$$[P_h]_z = (\rho - \rho_m) g (H - z) \quad (2)$$

Tectonic Stresses, σ_t

Trend selection of the dike. Dikes usually propagate normal to the direction of the least compressive stress and grow by infiltration of

Fig. 1b. Map of the Inyo Domes area showing rhyolitic domes, phreatic craters, faults, cracks, and caldera margins. Location marked in Figure 1a EF marks Earthquake Fault [after Fink, 1985].

magma into fractures [e.g., Anderson, 1938, 1951; Delaney *et al.*, 1986]. Host rock enclosing the tip of a growing dike is dissected by old, preexisting fractures as well as by new fractures induced by the propagating magma. The magma invades the fractures having the mechanically most favorable orientation, regardless of their origin.

The N07°W alignment of the young Inyo Domes chain appears unaffected by two large, preexisting tectonic features. The first large structure is the active system of normal faults that bound the Sierra Nevada block. One of these, the Hartley Springs fault, trends N30°W and intersects the Inyo chain along the west side of South Glass Creek Dome (Figure 1b). This fault indicates local horizontal extension in an N60°E direction (Figure 4a). The second large feature is the conspicuous marginal zone and associated deep-seated ring faults of Long Valley caldera. The ring fault system trends NE-SW at its intersection with the Inyo Craters chain between South Glass Creek Dome and South Deadman Dome

(Figure 1b) and thus indicates local horizontal extension in a NW-SE direction across the caldera margin (Figure 4a). No change in dome alignment, eruption style, or magma composition has been detected close to these two intersections [Miller, 1985; Fink, 1985; Sampson, 1987]. Thus the growing Inyo Dike seems to have ignored both the fractures and the stress axes associated with the largest nearby preexisting tectonic features.

During its propagation at depth z , the Inyo Dike intrudes fractures trending N07°W and ignores fractures trending NE-SW and N30°W of the preexisting systems (Figure 4a). This trend selection implies that the driving pressure (equation (1a)) is larger for the N07°W fracture trend than for the other two fracture trends. Of the six terms in (1a), only the tectonic stress, σ , varies with the fracture trend. Therefore we infer that the magma intruded the N07°W fractures because the tectonic stresses associated with this trend are more intrusion supporting than the tectonic stresses asso-

Fig. 2a. Schematic diagram showing inferred dike geometry beneath the Inyo Domes. Note that the dike is continuous at depth and segmented near the surface.

ciated with the other trends. We will examine this inference in detail.

In order for magma to invade an existing fracture, $P_f = 0$; that is, the magma pressure should exceed the stress normal to the fracture's surface. The orientation of vertical fractures that can be dilated by magma pressure, P_m , were determined from Mohr circle relations by *Delaney et al.* [1986, equation 1] (Figure 4a). They found that fractures trending at an angle α with respect to σ_3 would be dilated by the magma if

$$R = \{[(P_m - \sigma_1) + (P_m - \sigma_3) + 2(\rho, gz)] / (\sigma_1 - \sigma_3)\} > \cos(2\alpha) \quad (3)$$

where σ_1 and σ_3 are the principal horizontal tectonic stresses. The term $2(\rho, gz)$ appears in (3) because the magma pressure P_m is defined here as the deviatoric pressure in the dike (equation 2), whereas the magma pressure is defined by *Delaney et al.* [1986] as the absolute pressure in the dike.

Fig. 2b. Detailed schematic view of Obsidian Dome segment showing development of widened pipe in center of segment and termination of dike a few hundred meters below the surface.

The curves in Figure 4b are numerical solutions for the stress ratio R of (3) for the three dominant structural systems in the Inyo area, N07°W, N30°W, and N45°E (Figure 4a). For $R < -1$, the dike could not intrude any fracture, which indicates negative driving pressure; for $R > 1$, the dike could intrude all fractures. For $-1 < R < 1$ the dike intrudes fractures trending as plotted in Figure 4b. Each stress state is represented by a point on Figure 4b; for example, point G is for σ_1 trending N10°E and $R = 0.1$. The magma can only dilate a fracture if the point representing the stress state appears above the curve corresponding to that fracture. Consider σ_1 trending N10°E (solid line in Figure 4b). For R ranging from -1. to -0.95 the stress states are below all curves, and thus no fracture can be dilated; for $-0.95 < R < -0.4$ only trend a can be dilated; for $-0.4 < R < -0.15$ fractures trending a and b can be dilated, and for $R > -0.15$, all three trends can be dilated (Figure 4b). For this case, $\alpha_a = 17^\circ$, $\alpha_b = 40^\circ$ and $\alpha_c = 35^\circ$ (Figure 4a).

The observation that the Inyo Dike ignored the two preexisting structures indicates that it trends normal to the least compressive tectonic stress direction during the intrusion, N83°E. The development of the Inyo Dike along a trend which reflects a regional stress field rather than local structures is in agreement with other studies of paleostress; they show relatively uniform regional fields, on scales of tens to thousands of kilometers, which seem to ignore local structure [e.g., *Zoback and Zoback*, 1980; *Eyal and Reches*, 1983]. Further, the fact that the fractures oriented N30°W and N45°E were not intruded bounds the stress ratio: when the least compressive stress trends N83°E, the ratio is $-1.0 < R < -0.65$ (Figure 4b); for $R > -0.65$, fractures trending N30°W would also have been invaded.

Tectonic stresses in the eastern Sierra Nevada. Tectonic stress data are not available for the Long Valley area, so here we employ the regional stress analysis of *Zoback and Zoback* [1980, 1987]. They found that the Sierra Nevada region includes both strike-slip and normal faulting, and it is transitional between the San Andreas

Fig. 3. Detailed map of Earthquake Fault and adjacent ground cracks in southern part of the Inyo Chain. Location indicated in Figure 1b. Note pattern of bimodal fracture trends. Lines dashed where trends inferred.

strike-slip province and the Cordillera extension province (Figure 5). They stated that, "detailed observations of faulting in the region of combined normal and strike-slip faulting (including broadly the Sierra Nevada-northern Basin and Range boundary zone and the Walker Lane belt of western Nevada) suggest temporal variations (possibly quite large) in both stress orientation and relative magnitudes" [Zoback and Zoback, 1987].

For the strike-slip events the stresses are $\sigma_{Hmax} > \sigma_v \gg \sigma_{Hmin}$, and for normal faults the stresses are $\sigma_v > \sigma_{Hmax} \gg \sigma_{Hmin}$, where σ_v , σ_{Hmax} , and σ_{Hmin} are the vertical, maximum horizontal, and minimum horizontal stresses, respectively [Zoback and Zoback, 1987]. Using the results of McGarr and Gay [1978], we find for strike-slip faulting,

$$\begin{aligned} \rho_r gz < \sigma_1 < 1.5 \rho_r gz & \quad (\sigma_1 \text{ horizontal}) \\ \sigma_2 &= \rho_r gz & \quad (\sigma_2 \text{ vertical}) \\ 0.5 \rho_r gz < \sigma_3 < \rho_r gz & \quad (\sigma_3 \text{ horizontal}) \end{aligned} \quad (4a)$$

Fig. 4a. Idealized geometric relationship between the principal horizontal stresses, σ_1 and σ_3 , in the Inyo Dike area and trends of major local structural features: a, trend of Inyo Dike, N07°W; b, trend of Hartley Springs Fault, N30°W; c, local trend of Caldera margin, N45°E.

and for normal faulting [Zoback and Healy, 1984],

$$\begin{aligned} \rho_r gz &= \sigma_1 & \quad (\sigma_1 \text{ vertical}) \\ \sigma_2 &< \rho_r gz & \quad (\sigma_2 \text{ horizontal}) \\ 0.5 \rho_r gz &< \sigma_3 & \quad (\sigma_3 \text{ horizontal}) \end{aligned} \quad (4b)$$

The axes of σ_{Hmax} in eastern California and western Nevada trend mostly in a NNE to N-S direction with a few cases of NNW (Figure 5). The N07°W trend of σ_{Hmax} , deduced above for the Inyo Dike (heavy line in Figure 5), appears to correlate with the observed regional distribution of trends of σ_{Hmax} (thin lines in Figure 5).

Stress distribution with depth. To determine the depth distribution of the tectonic stresses we make the following deductions. (1) The state of stress in the region of the Inyo chain is defined by (4), where σ_{Hmax} trends N07°W and σ_{Hmin} trends N83°E. (2) As the crust is continuously deformed, the long-term tectonic stresses within the crust are represented by its yield strength. (3) The rocks in the upper 10 km yield by fracturing when subjected to high strain rates according to the Griffith-Coulomb criteria.

The yield strength of the crust is usually derived for two distinct rheologies: frictional resistance to shear along fractures in the shallow, brittle rocks, and steady state creep in the lower, ductile rocks [e.g., Kirby, 1983]. The transition between the two rheologic

Fig. 4b. The stress ratio required for dilation by magma intruding into cracks oriented in directions N07°W, N30°W, and N45°E (a, b, or c trends from above) (after equation (3)).

Fig. 5. The trends of the axes of maximum horizontal stress, σ_{Hmax} (thin, short lines), for western Nevada and eastern California; these trends were determined from in-situ stress measurements, earthquake focal plane solutions, and geological structures [after Zoback and Zoback, 1987]. The black square is the study area (Figure 1) and the thick, long line is the deduced trend of σ_{Hmax} for the Inyo Dike.

behaviors occurs at about 20-km depth in crust with normal heat flow but may occur as shallow as a few kilometers in regions of high heat flow [Morgan and Golombek, 1984]. The high heat flow in Long Valley caldera suggests that the ductile-brittle transition is shallow.

Yield strength profiles for the Inyo area are calculated in the appendix and presented in Figure 6. This figure shows the maximum shear stress, $\sigma_s = (\sigma_1 - \sigma_3)/2$, that can be supported by the crustal rocks for the heat flow and crustal properties listed in the appendix. Figure 6 indicates that the upper 3-4.5 km of the crust deform by frictional slip, that σ_s attains a maximum value of 24 MPa in the 3-4.5 km deep transition zone, and that σ_s decreases to about 3 MPa for heat flow of 300 mWm^{-2} , or vanishes for heat flow of 500 mWm^{-2} below a depth of about 10 km.

Pressure Drop due to Viscous Resistance, P_{vis}

The termination of the Inyo Dike at depths less than 620 m implies that the driving pressure vanished at some depth $0 < z < 620 \text{ m}$. By using the derived values of P_h (equation (2)) and σ_t (Figure 6), we calculate P_{con} and P_{vis} , which satisfy vanishing driving pressure at depths shallower than 620 m.

Rearranging (1b) for vanishing driving pressure yields

$$P_{con} = [P_h + \sigma_t - P_{vis}]_z$$

The solution for this equation is shown in Figure 7 by substituting the results of (2) and the appendix. The figure displays the values of P_{con} required to propagate a dike from a 10-km-deep magma chamber to the shown depths, for the marked P_{vis} , the pressure drop

gradients in the dike. For example, for $P_{vis} = 0.75 \text{ MPa/km}$, the dike would propagate from a 10-km depth and terminate 500 m below the surface if the constant pressure equalled 0.4 MPa. When $P_{con} > 0.4 \text{ MPa}$, the dike continues to propagate, and it would reach the surface for $P_{con} > 3.3 \text{ MPa}$. Figure 7 shows that for $P_{vis} = 0.5 \text{ MPa/km}$, the dike would reach the surface when $P_{con} = 0.8 \text{ MPa}$.

Figure 7 indicates that a significant increase of P_{con} is required to move a dike from a depth of a few hundred meters to the surface. This property reflects the profound decrease of the deviatoric tectonic stress, σ_t , toward the surface (Figure 6).

According to Figure 7, for the Obsidian Dome segment to terminate at depths between 250 and 600 m, the likely pressure conditions are included in the field marked I. This field is bounded by $0.5 < P_{vis} < 0.75 \text{ MPa/km}$ and $-0.5 < P_{con} < 1.8 \text{ MPa}$.

DEPTH-CONSTANT PRESSURES

Elastic Resistance, P_e

The Inyo Dike is envisioned as an elliptical, vertical crack, subjected to internal pressure, and embedded in an infinite, uniform granite. Similar configurations were analyzed by Weertman [1971] who studied crevasses in glaciers and magma transport in oceanic ridges, and Pollard and Muller [1976] and Gudmundsson [1983], who applied the results to forms of dikes.

A closed crack in an elastic plate subjected to a pressure difference of ΔP , between the internal hydrostatic pressure in the crack and the external hydrostatic pressure in the host rock, would dilate into an elliptical filled crack of width W and length L [Weertman, 1971, equation 15; Pollard and Muller, 1976, equation 6]. In the absence of tectonic stresses, the dimensions of the crack become

$$\Delta P = (W/L) [\mu/(1 - \nu)] \quad (5)$$

where μ and ν are the shear modulus and Poisson ratio of the elastic

Fig. 6. The yield strength of the upper 10 km of the crust in the Inyo area as derived in the appendix. The diagram indicates strength profiles for mean heat flow of (a) 500 mWm^{-2} and (b) 300 mWm^{-2} .

Fig. 7. The constant pressure, P_{con} , required to propagate a dike from a 10 km deep chamber to a depth of 2 km or shallower under a pressure drop of (a) 0.5 MPa/km and (b) 0.75 MPa/km. Under pressure drop of 0.75 MPa/km, P_{con} must exceed 3.3 MPa for the dike to vent to the surface. The field marked I bounds the conditions for a dike to terminate at a depth of 250-600 m below the surface.

plate. Equation (5) shows the pressure required to overcome the elastic resistance of the plate; thus $P_e = \Delta P$.

We substitute the following values for the Inyo Dike: $W = 7$ m, $L = 11$ km, $\mu = 20$ GPa, and $\nu = 0.1$ (granite), and find $P_e \approx 14$ MPa. Thus an internal pressure of 14 MPa (above lithostatic pressure in the granite) is necessary to dilate an 11-km-long fracture in granite into a 7-m-wide dike.

Fracture Strength, P_f

The fracture strength of the granite in the Inyo area may be estimated from the dimensions of the dike. The third drill hole of the Inyo drilling project [Eichelberger *et al.*, 1985] showed that the 7-m-thick segment of the Inyo Dike did not reach the surface and terminated at a depth of less than 620 m, about 1 km south of Obsidian Dome. On the other hand, the 35-m-thick pipe under Obsidian Dome extends to the surface (Figure 2b) [Eichelberger *et al.*, 1985, Figure 3].

Delaney and Pollard [1981] showed that magma transport in a quasi-circular pipe is more efficient than magma transport in a sheetlike dike. Thus piercement of the surface by the Obsidian Dome pipe and termination of the associated dike are expected. The dike and the pipe have the same composition [e.g. Vogel *et al.*, 1987] and most likely were fed by interconnected conduits during a single eruption (Figure 2). Thus during the eruption, a hydrostatic balance existed between the pipe and its associated dike. The hydrostatic pressure at the top of the dike [P_h]_{dike}, at depth $z = z_{top}$, is larger than the pressure at the top of the pipe [P_h]_{pipe}, at depth, $z = 0$,

$$[P_h]_{pipe} - [P_h]_{dike} = (\rho_r - \rho_m)gz_{dike}$$

for $\rho_r < \rho_m$ (equation (2)).

During the eruption of Obsidian Dome, the larger pressure at the top of the dike was not sufficient to propagate the dike upward, due to the resistance by the fracture strength of the granite P_f , the elastic resistance P_e , and the viscous resistance P_{vis} (equation (1a)). We assume here that the only resistance to propagation was the fracture strength of the host rocks, namely,

$$P_f = [P_h]_{pipe} - [P_h]_{dike}$$

Thus the calculated P_f is an upper limit for the strength. Taking $\rho_r = 2670$ kg/m³, $\rho_m = 2250$ kg/m³ (molten rhyolite [Williams and McBirney, 1979, p. 29]), and $z_{dike} = 250$ -600 m, we obtain an estimate of the fracture strength as 1-2.5 MPa. These values express the in situ, overall maximum resistance to yielding of the intruded rocks and may not be directly transformed into fracture toughness values.

Volatile Overpressure, P_v

Figure 7 shows that the constant pressure, P_{con} , ranges from -0.5 to 1.8 MPa for pressure drop due to viscous resistance of $0.5 < P_{vis} < 0.75$ MPa/km. The fracture strength and the elastic resistance were determined above from the dike dimensions, and now the volatile overpressure, P_v , can be estimated.

Equation (1b) indicates that

$$P_v = P_{con} + P_f + P_e$$

By substituting the above derived values of $-0.5 < P_{con} < 1.8$ MPa, $1 < P_f < 2.5$ MPa, and $P_e \approx 14$ MPa into this equation, we find a volatile overpressure which ranges from 14.5 to 18.3 MPa.

THE DRIVING PRESSURE OF THE INYO DIKE

We examine here the depth variations of the driving pressure of the Inyo Dike (equation (1a)), after the above derivation of all its six pressure components. We use the following parameters and results.

1. We assume that the tectonic shear stresses are equal in magnitude and distribution to the shear strength of the crust (appendix and Figure 6).

2. The tectonic stresses in the Sierra Nevada province are either of strike-slip faulting (equation (4a)), or of normal faulting (equation (4b)). To simplify the following analysis, we suppose that during the intrusion of the Inyo Dike, the stresses around Long Valley were of strike-slip faulting (we will establish this assumption below) (equation (4a)), so that

$$\sigma_{Hmax} > \sigma_v > \sigma_{Hmin} \quad (6)$$

By substituting (6) into (4a), one gets $\sigma_1 + \sigma_3 \approx 2(\rho_r gz)$, and thus the stress ratio of (3) becomes

$$R \approx P_m / \sigma_s \quad (7a)$$

Equations (4a) and (6) also indicate that $(\sigma_1 + \sigma_2 + \sigma_3)/3 \approx \rho_r gz$, and thus

$$\sigma_i \approx \sigma_3 - (\rho_r gz) \approx -(\sigma_1 - \sigma_3)/2 = |\sigma_s| \quad (7b)$$

where P_m is the deviatoric magma pressure, σ_i is the deviatoric tectonic stress normal to the Inyo Dike, and $\sigma_s = (\sigma_1 - \sigma_3)/2$, the crustal shear strength.

3. The parameters of the host rocks are: density $\rho_r = 2670$ kg/m³, shear modulus $\mu = 20$ GPa, and Poisson ratio $\nu = 0.1$ (mean values for granitic rocks in [Clark, 1966]). The density of the rhyolitic magma $\rho_m = 2250$ kg/m³ [Williams and McBirney, 1979, p. 29].

4. Dimensions of the dike are: width $W \approx 7$ m, length $L \approx 11$ km, and depth of source $H \approx 10$ km.

Fig. 8. The depth variations of the driving pressure P_d , the magma pressure P_m , the tectonic stress σ_t , and the ratio $R \cong P_m/\sigma_t$ of the Inyo Dike according to the present analysis; the solution is for $P_{vis} = 0.55 \text{ MPa/km}$, $P_v = 14.5 \text{ MPa}$, $P_f = 1 \text{ MPa}$, and $P_s = 14 \text{ MPa}$ (see text). (a) Deviatoric pressures (minus the lithostatic load), (b) absolute pressures, and (c) ratio R of the deviatoric pressures (equation (7a)).

Fig. 9. The coordinate system for stresses at the tip of a pressurized crack. The Y-Z plane is normal to the planar crack. For the Inyo Dike, axis X is the σ_1 axis (horizontal and trending N07°W), axis Y is the σ_2 axis (vertical), and axis Z is the σ_3 axis (horizontal and trending N83°E).

5. The following parameters were estimated in the above analysis: pressure drop due to viscous resistance $P_{vis} = 0.5\text{--}0.75$ MPa/km, overpressure in the magma chamber $P_v = 14\text{--}18$ MPa, fracture strength $P_f = 1\text{--}2.5$ MPa, and elastic resistance to dike emplacement $P_e \approx 14$ MPa.

We now examine depth variations of the driving pressure P_d (equation (1a)), the magma pressure P_m (equation (1c)) and the ratio R (equation (7a)). At the depth of the magma chamber, H , the dike intruded only the N07°W fractures (see Figure 4b and text); thus

$$-1.0 < R < -0.95 \quad z = H \quad (8a)$$

At depths shallower than 620 m where the dike stopped, no fracture was dilated; thus

$$R < -1.0 \quad z < 620 \text{ m} \quad (8b)$$

Using the conditions of (8) and substituting the pressures listed in the paragraph above into (1) and (6), we derive the solution displayed in Figure 8. The deviatoric pressures P_d , P_m , and σ_1 are shown in Figure 8a, their absolute values (including the lithostatic load) are shown in Figure 8b, and the ratio $R \equiv P_m/\sigma_1$ is shown in Figure 8c. The solution in Figure 8 is for $P_{vis} = 0.55$ MPa/km, $P_v = 14.5$ MPa, $P_f = 1$ MPa, and $P_e = 14$ MPa; this solution fits best the conditions of (8) and is bounded by the pressures derived above.

In this solution, the deviatoric magma pressure P_m changes linearly with depth from -0.45 MPa at 10-km depth to -1.7 MPa at the surface (dotted line in Figure 8a), and the deviatoric tectonic stress varies nonlinearly with depth as derived in the appendix (thin line in Figure 8a). The driving pressure is the difference between the two pressures, $P_d = P_m - \sigma_1$ (solid line in Figure 8a). The driving pressure is positive for all depths below 500 m (namely, it supports dike intrusion), and negative for depths shallower than 500 m.

DISCUSSION

In the preceding analysis, we incorporated the depth variations of tectonic stresses in the Inyo area and estimated separate components of driving pressure of the Inyo Dike. We discuss below how these results may explain the rotation of segments of the Inyo Dike.

Dike Segmentation and Rotation

A propagating dike generates a local, nonuniform stress field close to its tip which modifies the uniform tectonic stress in the host

rock. The principal stresses of the nonuniform field in front of the dike tip are tensional for positive driving pressure, $P_d > 0$ [e.g., Jaeger and Cook, 1969, section 10.12]. We argue here that the reduction of tectonic stresses associated with these tensional stresses may explain segmentation of the Inyo Dike and rotation of its segments.

A dike may be modeled as a pressurized crack completely filled with magma or as a pressurized crack with a leading mode I crack which is not completely filled with magma. The stress field in the host rock is essentially identical for both configurations (compare (Jaeger and Cook, [1969, section 10.12] for pressurized crack and Lawn and Wilshaw [1975, equation 3.11], for mode I crack).

The stresses in a plane normal to a planar crack pressurized uniformly by magma, under plane strain conditions (Figure 9), were calculated by Jaeger and Cook [1969, section 10.12] and Lawn and Wilshaw [1975, equation 3.11]. For the Inyo Dike, axis X is the σ_1 axis (horizontal and trending N07°W), axis Y is the σ_2 axis (vertical), and axis Z is the σ_3 axis (horizontal and trending N83°E). The stresses are,

$$\begin{aligned} \sigma_{xx} &= (P_m - \sigma_1)(0.5C/r)^{1/2} \{ \cos(\phi/2) [1 + \sin(\phi/2) \sin(1.5\phi)] \} \\ \sigma_{yy} &= (P_m - \sigma_1)(0.5C/r)^{1/2} \{ \cos(\phi/2) [1 - \sin(\phi/2) \sin(1.5\phi)] \} \\ \sigma_{zz} &= (P_m - \sigma_1)(0.5C/r)^{1/2} \{ \cos(\phi/2) [\sin(\phi/2) \cos(\phi/2) \cos(1.5\phi)] \} \\ \sigma_{xz} &= v(\sigma_{xx} + \sigma_{yy}) \end{aligned} \quad (9)$$

where C is the dike length, r the distance from the dike tip, and ϕ the angle with the dike surface (Figure 9). As pointed out by Jaeger and Cook [1969, p. 263], for $P_m > \sigma_1$, the principal stresses in front of the dike, $\phi \neq 0$, and close to it, $C/r > 2$ (Figure 9), are tensile. This profound reduction of the principal stresses strongly affects the style of fracturing in front of the dike as discussed below.

The Sierra Nevada granites fracture according to the Griffith-Coulomb yield criteria which predict two modes of fracturing: extensional fractures for $(\sigma_1 + 3\sigma_3) < 0$ (conditions of small shear stresses and tensional σ_3 as shown by Mohr circle B in Figure 10b), and shear fractures when $(\sigma_1 + 3\sigma_3) > 0$ (conditions of large shear stress and large mean stress, $(\sigma_1 + \sigma_3)/2$ as shown by Mohr circle A in Figure 10a).

Consider the Inyo Dike as it propagates upward at about 10-km depth. The tectonic stresses at this depth are $\sigma_1 \approx 268$ MPa and $\sigma_3 \approx 266$ MPa (Figures 6 and 10b). (The Mohr circles in Figure 10 are not to scale. A circle for the stress state at 10-km depth with $\sigma_1 \approx 268$ MPa and $\sigma_3 \approx 266$ MPa would be too small to see.) The magma intrudes into rocks subjected to large lithostatic stress and small differential stress; this state of stress is represented by Mohr circle b in Figure 10b. The reduction of the stresses in front of the dike to become tensile shifts the Mohr circle b to a new Mohr circle B (Figure 10b). This shift causes the circle to touch the Griffith-Coulomb failure envelope at a position which indicates the formation of vertical extension fractures trending N07°W, perpendicular to the least compressive stress [see Secor, 1965; Julian and Sipkin, 1985, Figure 16]. The dike may now intrude into those fractures (Figure 10d).

During its upward propagation at a depth of 3.5 km the dike encounters a large tectonic shear stress of about 15 MPa, displayed by Mohr circle a in Figure 10a. The reduction of stresses in front of the dike again shifts the Mohr circle a leftward to a new Mohr circle A (Figure 10a). However, here the shifted Mohr circle touches the failure envelope at a position which indicates failure by shear fractures (Figure 10c). Under the tectonic stress of the Inyo area (equation (6)), the shear fractures would be vertical strike-slip faults (Figure 10c). Extension fractures do not form in the transition zone due to its large initial shear stresses.

Fig. 10. (a and b) Schematic Mohr diagrams for the fracturing of crustal rocks during the propagation of the Inyo Dike (see text). The heavy curve is the Griffith-Coulomb yield envelope. Circles b and B (in Figure 10b) indicate the states of stress prior to and after the intrusion of the dike at depths of 10 km (see text). Note that circle B indicates extensional fracturing. Circles a and A (in Figure 10a) indicate the states of stress prior to and after the intrusion of the dike at a depth of 3 km (see text). Note that circle A indicates shear fracturing. (c) The geometry of the faults anticipated from the yielding shown by circle A, displayed in a block diagram (left) and a stereographic projection (right). (d) The geometry of the faults anticipated from the yielding shown by circle B, displayed in a block diagram (left) and a stereographic projection (right).

The conditions under which the Inyo Dike could dilate these shear fractures are delineated by (3) and Figure 4b. A vertical shear fracture which strikes from N20°W to N18°E may be intruded by the dike for stress ratios R larger than -0.7 (Figure 4b); our calculations of R (Figure 8c) indicate that at 3-km depth $R \approx -0.2$ which is sufficient to dilate the predicted shear fractures.

The change in the mode of fracturing invokes a change in the trend of the dike. The deep extensional fractures trend N07°W (Figure 10d), whereas the upper shear fractures trend in the range N37°W to N23°E (Figure 10c). Therefore the passage of magma from the deep extensional fracture to the shallower shear fractures allows for rotation of the dike segment in the transition zone. The change in the fracturing mode would occur at several locations

along the tip of the Inyo Dike in the transition zone. Thus intrusion of the magma into the rotated shear fractures also would occur in several locations and the dike should have split into several segments (Figure 2).

In summary, the process described above demonstrates that the Inyo Dike would have propagated from the magma chamber in self-induced extensional fractures due to small shear stress in the ductile region of the crust (Figures 10b and 10d). In the transition zone from ductile to brittle rheology, at a depth of about 3 km, the mode of fracturing changes from extensional to shear due to the large shear stresses (Figures 10a and 10c). The dilation of shear fractures rather than extension fractures results in rotation of the dike and segmentation (Figure 2). We thus conclude that segmentation and

Fig. 11a. Map of Tarawera Dome complex showing observed and inferred positions of en echelon basaltic dike segments (dark lines) that erupted in 1886. Map location shown in Figure 10b [after Nairn and Cole, 1981].

rotation may be the consequences of changes in rheology and fracturing mode of the crust in a region of high heat flow.

The proposed mechanism of dike intrusion into shear fractures explains and is supported by several observations.

1. The trends of surface fractures in the Inyo area display bimodal distributions. This is apparent in the map of large-scale faults and fracture zones (Figure 1b), as well as in the details of one fracture zone, the Earthquake Fault (Figure 3). Although direct inclinations are difficult to measure, all exposed fractures are very steep to vertical. We interpret these fractures as incipient sub-vertical strike-slip fractures which have been dilated. The vertical attitude and the bimodal trend distribution support the above suggestion that the strike-slip stress conditions existed during the Inyo Dike intrusion (equation 6); however, unambiguous shear displacements have not been documented.

2. The Obsidian Dome segment of the Inyo Dike seems to rotate gradually as it rises. Surface mapping suggests a trend of about $N18^{\circ}E$ (Figure 1b), whereas the drill core indicates a trend of $N06^{\circ}E$ at 620-m depth (Figure 2b) [Fink, 1985]. The inclination of the segment is unknown. If the rotation in the upper 620 m is part of a uniform, gradual rotation from the main Inyo Dike, then this segment should merge with the $N07^{\circ}W$ trending main dike at a depth of about 1200 m. The calculations in the above section for depth of the transition zone indicated 3 km; we regard these depths as bounding values.

3. Most segments of the Inyo Dike appear to be rotated clockwise, with the possible exception represented by the NNW trending fracture zone southeast of Deer Mountain [Mastin and Pollard, in press] (Figures 1b and 2). We speculate that this preferred sense of rotation is caused by release of shear stress along intruded shear fractures. Both clockwise and counterclockwise trending shear fractures would be available in the transition zone (Figure 10c). If a clockwise trending fracture were intruded first by the magma, then shear stress parallel to the fracture would relax. Relaxation of the shear stress causes a local rotation of the horizontal principal stress axes in a clockwise sense. Because such stress rotation increases the tendency of clockwise fractures to be intruded by the magma, the process will amplify itself, leading to eventual domination by one trend.

Applications of the Present Analysis

Even though the present analysis is based on measurements in and around the Inyo Chain, it may provide some insight into other sheet intrusions in Long Valley caldera and elsewhere.

Rotated segments of dikes and sills have been observed in many locations [e.g., Pollard et al., 1975; Delaney and Pollard, 1981]. Pollard et al. [1982] proposed that segment rotation occurs in response to rotation of the least compressive stress axis. We have demonstrated here that the rotation may also occur due to variations in host rock rheology and fracturing style.

One prediction of the current model is the occurrence of bimodal fracture patterns accompanying dike intrusion as manifested along the Inyo trend in the detailed structure of Earthquake Fault (Figure 3). Similar bimodal fracture patterns occur in other sites above shallow dikes. The Tarawera eruption of 1886 in New Zealand was fed by a 30-km-long $N30^{\circ}E$ trending basaltic dike whose segments show a consistent clockwise rotation of 15° (Figure 11a) [Nairn and Cole, 1981]. Regional mapping in the Tarawera area reveals two main sets of faults oriented $N10^{\circ}E$ and $N45^{\circ}E$ (Figure 11b) [Wilson et al., 1984]. A second example is provided by ground cracks along the trend of Little Glass Mountain and adjacent rhyolite domes of the Medicine Lake Highland Volcano in California. The patterns of vents and faults indicate a NE trending dike whose segments rotated clockwise [Fink and Pollard, 1983]; in detail however, the fracture pattern shows a bimodal distribution (Figure 12). These patterns indicate possible application of the present model, but additional study is required to fully ascertain this suggestion.

Our study also offers an explanation for two controversial geophysical observations in Long Valley caldera. The first case concerns the analysis of focal mechanisms for three earthquakes that occurred in 1980 at depths of 7-10 km, south of the caldera (locations shown in Figure 1a). One interpretation implies that these are double-couple shear events associated with complex shear surfaces [Wallace, 1985; Lide and Ryall, 1985; Priestly et al., 1985], whereas the alternative model suggests that these events indicate dilation phenomena associated with rapid intrusion of magma into NNW-SSE trending cracks [Julian and Sipkin, 1985;

Fig. 11b. Map of faults in the vicinity of Tarawera Complex, New Zealand. Note bimodal distribution of orientations. Shaded areas, silicic volcanic rocks; dashed line, margin of caldera [after Wilson et al., 1984].

Fig. 12. Map showing ground cracks over inferred northeast trending silicic dike(s) northeast of Little Glass Mountain rhyolite flow on the Medicine Lake Highland Volcano, California. Features indicated on the inset map include Little Glass Mountain (LGM), Big Glass Mountain (BGM), Crater Glass Flow (CG), Medicine Lake dacite flow (MF), Medicine Lake (ML), caldera margin (dotted line), and ground crack trends (dashed lines). On main crack map, segments with more than 5-m horizontal separation indicated by dotted lines. Note zigzag pattern of crack trends.

Chouet and Julian, 1985]. The second interpretation is in accord with the present analysis that predicts extensional fracturing due to magma intrusion as deep as 10 km.

The second set of controversial observations involves recent deformation data collected within Long Valley caldera. Savage and Cockerham [1984] showed that ground deformation that occurred in 1983 could be explained by the dilation of an intrusive body extending from a depth greater than 10 km to a level about 3 km below the surface. Although the explicit shape of the intrusion could not be uniquely resolved, they indicated that the deformation could be accounted for by inflation of a sill inclined 30° between depths of 12 and 8 km that fed a vertical dike extending from depths

of 8–3 km. The observed surface deformation would require 0.39-m inflation of the sill and 0.15 m for the dike.

The model of Savage and Cockerham raises the question as to why magma should rise from depths of 12 km to within 3 km of the surface without erupting. If an intrusion in 1983 had dimensions on the order of tens of centimeters, it would have frozen before reaching the surface. However, our analysis indicates that even for a width on the order of 10 m (for which the cooling rate would not be significant), an intrusion could not reach the surface unless the volatile overpressure exceeded the host rock fracture strength by at least 18 MPa. This constraint is supported by the pattern of Holocene silicic activity in the Inyo and Mono Craters areas where

magma approached the surface in several long dikes but erupted only from wide pipelike vents such as the one penetrated by drilling beneath Obsidian Dome.

CONCLUSIONS

The analyses presented here indicate the following:

1. Stress fields of continental scale may prevail and control dike orientation even in the vicinity of large and active tectonic features.
2. Variations in crustal rheology and the related variation of fracturing style may cause segmentation and rotation of dikes without direct rotation of the stress axes. Thus trends of dike segments may be indicators of rheology as well as of stress orientation.
3. Dike geometry provides bounds on the mechanical parameters of intrusion. For the Inyo Dike we find that extensional fracture strength is 1-2.5 MPa, the elastic resistance to dike intrusion is about 14 MPa, the volatile overpressure in the magma chamber is 14-18 MPa, and the pressure drop in the propagating dike is about 0.55 MPa/km.
4. Propagation of dikes becomes increasingly difficult as they near the surface due to the upward decrease in tensile strength and the corresponding reduction in tensile stress magnitude. Cessation of dike rise may thus result from an upward decrease in the influence of regional tensile stresses, rather than from cooling and solidification. This process may explain why the Inyo Dike stopped rising only a few hundred meters below the surface at the Inyo Craters and at the site of the RDO-3A drill hole.

APPENDIX

We derive here the crustal strength variations with depth in the vicinity of the Inyo chain using the following procedure: (1) calculate the depth/temperature profile, (2) calculate the frictional strength of the crust, assuming it varies linearly with depth and it is independent of temperature or rock type, and (3) obtain the yield strength for steady state creep by assuming power law rheology.

The first step is calculating the temperature profile. Following Turcotte and Schubert [1982, equation 4-31],

$$T = T_s + \frac{Q_m}{k} (h/k) + \frac{(Q_s - Q_m)H}{k} [1 - \exp(-h/H)] \quad (A1)$$

where T_s is surface temperature, Q_m and Q_s are the heat flow of the mantle and the surface, respectively, h is the depth, H is characteristic depth length, and k is the thermal conductivity. The details of the geothermal system in Long Valley caldera are partly obscured by the intensive hydrothermal activity [Sorey, 1985; Blackwell, 1985]. Furthermore, the Inyo Chain is partly outside the caldera (Figure 1a), and thus the data collected in the caldera may serve only as an estimate. The mean heat flux in the Long Valley caldera, calculated by dividing the total heat discharge by the caldera area, is 630 mW m⁻² [Sorey, 1985, Table 1]. The thermal conductivity k ranges from 1.05 W m⁻¹ K⁻¹ for the post-Bishop Tuff rocks [Blackwell, 1985, p. 11, 236] to 3.1 W m⁻¹ K⁻¹, the mean thermal conductivity for granite [Clark, 1966], which is the basement rock in the Inyo area [Eichelberger et al., 1985].

We take for the Inyo area two bounding values of surface heat flow, $Q_s = 300$ mW m⁻² and $Q_s = 500$ mW m⁻², thermal conductivity of $k = 3.0$ W m⁻¹ K⁻¹, and also $T_s = 10^\circ$, $H = 10$ km, and $Q_m = 30$ mW m⁻² [Turcotte and Schubert, 1982]. The calculated temperatures are used as input for (A2) below.

The second step is calculating yield strength for steady state creep of crustal rocks from the power law creep equation [Weertman and Weertman, 1975] as modified for crustal flow by Lynch and Morgan [1987],

$$\sigma_1 - \sigma_3 = (E/E_0)^{1/n} \exp[(Q + PV)/(nRT)] \quad (A2)$$

where σ_1 and σ_3 are the maximum and minimum principal stresses, E is the strain rate, E_0 and n are rock constants, Q is the activation energy, V is the activation volume, P is the pressure, R is the gas constant, and T is the temperature [see also Kirby, 1983]. Following Lynch and Morgan [1987, Tables 1 and 2], $n = 3$, $PV = 293$ J/mol km, and for siliceous rocks, $Q = 1.4 \times 10^5$ J/mol and $E_0 = 2.5 \times 10^{-8}$ MPa³ s⁻¹. By substituting these values and the temperatures derived from (A1) into (A2), we determine the lower part of the strength curves shown in Figure 6.

The third step is determining the strength of the brittle part of the crust due to frictional resistance along shear fractures. For extensional conditions it is 5.5 MPa/km [Lynch and Morgan, 1987]. This strength composes the upper part of the curve in Figure 6.
