Abstract

Study of northwest Alaskan ceramic production and distribution patterns has the potential to provide new evidence of coastal hunter-gatherer mobility and social interaction in the late pre-contact period. This research is directed at characterizing potential clay sources and linking ceramic groups to raw-material source areas through instrumental neutron activation analysis (INAA) and modeling of possible clay and temper combinations. Results of INAA of 458 ceramic, 31 clay, and 28 possible temper specimens reinforces prior identification (Anderson et al., 2011) of three broad compositional groups. Though raw materials were collected over a large area, the clay specimens demonstrate remarkable geochemical homogeneity and fall within one of the established ceramic geochemical groups, Macrogroup 2. This suggests that potters may have added little to no mineral temper to the clays and also that what we have termed Macrogroup 2 ceramics were produced in the north and central areas of northwest Alaska. Group 1 and 3 ceramics may be evidence of pottery being brought into the region from elsewhere. Results indicate that ceramics circulated widely around the region and suggest the possibility of areas of greater production perhaps due to an abundance of clay or wood fuels needed for firing. This work lays the foundation for further exploring the cultural processes that underlie these distributions and provides insight into the complexities of hunter-gatherer ceramic production and distribution.

Keywords: hunter-gatherers; mobility; exchange; ceramics; neutron activation analysis; Arctic

1.0 Introduction

Hunter-gatherer ceramic artifacts are relatively rare (see Jordan and Zvelebil, 2009 for summary), but study of their distributions provides new insights into mobility, social interaction, and technological organization (e.g., Eerkens, 2001, 2002, 2003; Eerkens et al., 2002; Simms et al., 1997). Compositional analysis of North American Arctic ceramic technology presents an opportunity to study coastal hunter-gatherer mobility and social interaction during the late Holocene, a period of significant environmental and social change in the northwestern Arctic (Figure 1). Over at least the previous 3,000 years, coastal occupation increased and people developed specialized maritime tools and subsistence strategies. There is evidence of increasing social difference as well as complex socioeconomic structures that connected people across the region and beyond through extensive travel and trade. Compositional analysis can help archaeologists study the changing geography of these networks over time, illuminating how and why people maintained such extensive interaction networks during the Late Holocene. The goal of this paper is to characterize potential clay sources and to link ceramic groups to raw-material source areas through instrumental neutron activation analysis (INAA). The results of this work establish a foundation for studying the cultural processes involved in Arctic ceramic distribution and the social networks they represent. This work has broader implications for understanding hunter-gatherer ceramic technology, mobility, and the role of social interaction in complex hunter-gatherer groups.

2.0 Prior Work

Prior to our 2011 pilot study (Anderson et al., 2011), it was not clear if the exchange of ceramic artifacts was part of prehistoric distribution networks in northwest Alaska. While there is historic evidence of ceramic trade, the antiquity of this practice was unknown. Ceramic technology was adopted from western Beringia about 2,800 years ago (see Ackerman, 1982; Frink and Harry, 2008 for additional summary). Early ceramics are thin, relatively hard, have a globular shape, and are decorated in characteristic linear, check-stamp, or cord-marked styles. This early ceramic tradition is quite different from later, post-1500 BP Arctic ceramics. Post-1500 BP ceramic vessels are thick, softer, cylindrical or flower-pot shaped and often undecorated. Ceramics are much more abundant after 1500 BP. The rough appearance of later ceramic cooking vessels suggests expedient production and local use, but a pilot study that included INAA of 99 ceramic specimens from northwest Alaska established that hunter-gatherer ceramics were part of distribution networks over at least the last 1,000 years (Anderson et al.,

2011). This work also demonstrated the potential of ceramic research for addressing questions about Arctic hunter-gatherer lifeways. Questions remained, however, about the location of production areas and the nature of interaction networks. Analysis of a larger sample of ceramics was needed. The study presented here builds on the earlier pilot project by including a larger sample which also incorporates raw clay and temper materials collected from across the region.

42

43 **3.0 Samples**

44 *3.1 Ceramics*

45 This study relies on existing ceramic collections from northwest Alaska. The advantage of this
46 approach is that it allows significant temporal and geographic expansion of the project. The
47 disadvantages of using museum collections include variation in sample sizes from sites available for
48 study, limited provenience and contextual information, and limited information on collection methods
49 in some cases. Information was most limited for collections made by Giddings in the 1940s and 50s at
50 Kotzebue and along the Kobuk River (Giddings, 1952), but the value of including these relatively large
51 collections from otherwise unstudied areas of northwest Alaska outweighed the disadvantages. A total
52 of 8,395 ceramic specimens from 17 sites spanning the study period (

53 Table 1) were classified according to various technological and decorative attributes using
54 standard ceramic analysis methods (e.g., Rice, 1987). A subsample of specimens for INAA was selected
55 from each site based on the nature and size of primary temper, exterior color, and exterior surface
56 treatment (Anderson, 2011). Rim sherds were preferentially selected for analysis to limit the potential
57 of sampling the same vessel twice. An additional 360 ceramic specimens were submitted for analysis by
58 neutron activation as part of this study, bringing the total sample to 458 specimens¹.

59

60 *3.2 Clay and Temper Samples*

61 Although study of ceramic production and distribution patterns is possible without direct
62 comparison to geological samples of clay from potential source areas, analyses of clays can aid in
63 connecting ceramic geochemical groups to production locales (Eerkens, 2002; Quinn et al., 2013).
64 Additionally, surveys directed at identifying raw materials for ceramic production can yield information
65 about the availability and suitability of clays at both local and regional scales. A clay survey was
66 conducted as part of this project to aid in identifying ceramic distribution patterns and to gain insight
67 into potters' choices during the production process. Survey design was informed by ethnographic data
68 on clay sources (Anderson, accepted), by available geologic information, and by logistical issues
69 associated with working in remote areas of northwest Alaska. Identification and sampling of reported
70 and possible sources near the archaeological study sites were priorities. Survey was conducted along
71 the Kobuk River and its tributaries, along the northern coast, and in several areas of the southern coast
72 and interior (Figure 2). A total of 40 clay specimens and 39 possible temper specimens were collected

¹ Specimen SLA 244, though submitted for analysis, was of insufficient mass for reliable analysis by neutron activation using standard University of Missouri Research Reactor procedures.

73 during the survey, and two additional clay specimens were provided by colleagues. Of these, 28 temper
74 and 31 clay specimens were submitted for geochemical analysis (Table 3).

75
76 Collection methods and an in-depth discussion of survey results are detailed elsewhere
77 (Anderson, accepted); however, key findings of the survey that are important for interpreting these
78 geochemical analyses are as follows. First, clays suitable for making pottery are not universally available
79 across the study area. For example, few clay deposits appropriate for pottery making were identified in
80 the southern part of the study area. Second, there is considerable variability in clay quality and in the
81 nature and density of aplastic inclusions within a given geological deposit. Third, not all sources of clay
82 were used by Native Alaskan potters, despite being located in close proximity to archaeological sites. In
83 sum, these findings suggest that even though geological deposits of clay are widespread, access to
84 suitable or desirable clays may have been restricted by cultural factors such as the season of site
85 occupation, the extent of a particular group's territory, and the nature of intergroup relationships within
86 the region.

96

97 **4.0 Methods**

98 Analyses of the ceramic, clay, and temper specimens were performed at the University of
99 Missouri Research Reactor (MURR) by the Archaeometry Laboratory, and protocols for sample
100 preparation, irradiation, and gamma-ray spectroscopy followed established procedures (Glascock, 1992;
101 Glascock and Neff, 2003; Neff, 2000). The interpretation of compositional data obtained from the
102 analysis of archaeological materials is discussed in detail elsewhere (Baxter and Buck, 2000; Bieber et al.,
103 1976; Bishop and Neff, 1989; Glascock, 1992; Harbottle, 1976; Neff, 2000) and is not summarized here.
104 Statistical analyses employed for identification of ceramic and clay geochemical groups included
105 principal component analysis and Mahalanobis distance calculations. Compositional data generated for
106 clay and temper specimens were combined to model potential ceramic compositions following methods
107 outlined by Neff et al. (1988).

108

109

110 **5.0 Results**

111 *5.1 Ceramics*

112 Analyses of the additional 360 ceramic specimens reinforce our prior identification of three
113 broad compositional macrogroups (Anderson et al., 2011). Principal components analysis indicates that
114 greater than 90% of the cumulative variance in the 458-specimen ceramic sample can be explained by
115 seven components (Table 4). The first principal component (PC) is positively loaded on Cs, Ta, and Rb,
116 and negatively loaded on transition metals such as V, Co, and Cr (Figure 3). Subgroupings developed in
117 the pilot study were refined with this additional analysis; many of the outliers to Macrogroups 1 and 2
118 were successfully reassigned, and Subgroup 2e was entirely eliminated. The majority of specimens can
119 be assigned to the remaining groups and subgroups (Table 5). Ninety-five specimens (20.7%) remain
120 unassigned to any compositional group. In compositional studies of this size and scope, this is not an
121 unreasonable number of unassignable specimens. They could represent ceramic products from exotic
122 or distant sources, or they could reflect sampling issues (e.g., local sources that are insufficiently
123 represented in the present sample).

124

125

"ii-iii" notation indicates uncertain date range versus II-III, which indicates transitional dates

137

138 Eight specimens (Table 6) in the dataset are characterized by a significantly lower
139 concentration of Al relative to all other specimens ($\mu = 1.62 \pm 0.77\%$). Of these, six specimens
140 (SLA024, 025, 67, 135, 139, 284) are enriched in transition metals Cr and Co, as well as being
141 characterized by significant Al depletion. The concentrations of Cr ($\mu = 2160.4 \pm 347.7$ ppm) and
142 Co ($\mu = 76.7 \pm 3.9$ ppm) are the highest in the entire dataset. When combined with significant
143 depletion in the rare earth elements (REEs) and alkali metals (Na, K, Rb, and Cs), these chemical
144 characteristics are highly distinctive (Figure 4). Only two archaeological sites are represented by
145 these six specimens: Ambler Island (n = 4) and Cape Krusenstern (n = 2). Three of the four
146 specimens from Ambler Island are from the same house feature. Considering that the lowest
147 observed Al concentration in the sampled clays is 5.38% (SLA366, collected from a tributary of
148 the Kobuk River), it is reasonable to conclude that none of the sampled clay sources were used
149 in the production of these sherds. Of the eight low Al specimens, two (SLA 356 and SLA 511)
150 may eventually form the basis for a new compositional group. These two specimens are also
151 depleted in Al, but their REE abundances and concentrations of transition metals are similar to
152 the majority of other ceramic specimens analyzed here.
153

155

156 Figure 4. Bivariate plot of Cs versus V concentrations in the northwestern Alaska ceramic
 157 dataset. Ellipses are drawn at the 90% confidence interval.

158

159

160

161 Table 6. Eight Specimens Comprising the Low-Al Compositional Group

| ANID | Context |
|--------|--------------------------------------|
| SLA024 | Ambler Island, House 7 |
| SLA025 | Ambler Island, House 7 |
| SLA067 | Cape Krusenstern, House 1B |
| SLA135 | Ambler Island, House 7 |
| SLA139 | Ambler Island, House 10 |
| SLA284 | Cape Krusenstern, Surface Scatter 1B |
| SLA356 | Agiagruat, Feature 6 |
| SLA511 | Cape Espenberg, 7N 8E |

162 Note that specimens SLA356 and SLA511 have significantly lower transition-metal abundances, and
 163 therefore likely represent a different provenance or ceramic recipe.

164

165 *5.2 Clays*

166 All of the clay specimens analyzed here are geochemically most similar to Group 2c, with the
 167 exception of SLA393 (collected in the lower Kobuk River region), which is most similar to Group
 168 2a (Figure 5). We used the geochemical data generated for clay and temper specimens in a
 169 mixture model to generate compositional profiles that represent ceramic products produced
 170 using each raw material. The goal of the modeling process was to explore how people may have
 171 used the raw materials we collected during the raw-material survey. Potential tempering
 172 materials (mineral grit and sand) were combined with clays from that same locality in 10%
 173 increments from zero (pure clay) to 50% (half temper and half clay, by mass). Modeled ceramic
 174 compositions were then projected against the various compositional groups proposed by
 175 Anderson et al. (2011). Group-membership probabilities based on Mahalanobis distance using
 176 33 elemental abundances were calculated for each modeled ceramic composition
 177 (Supplementary Information 1).

178

179 Results of this modeling process suggest that all of the clays and clay/temper mixtures are most
 180 similar, in general, to our compositional Macrogroup 2, and specifically to Groups 2a and 2c.
 181 None of the modeled ceramics produced compositions similar to Group 1 or to Group 3,
 182 suggesting that these two compositional groups comprise pottery produced with resources that
 183 were not sampled during the survey. Given the coverage of the survey, it is possible that both
 184 of these compositional groups represent non-local ceramic artifacts.

185

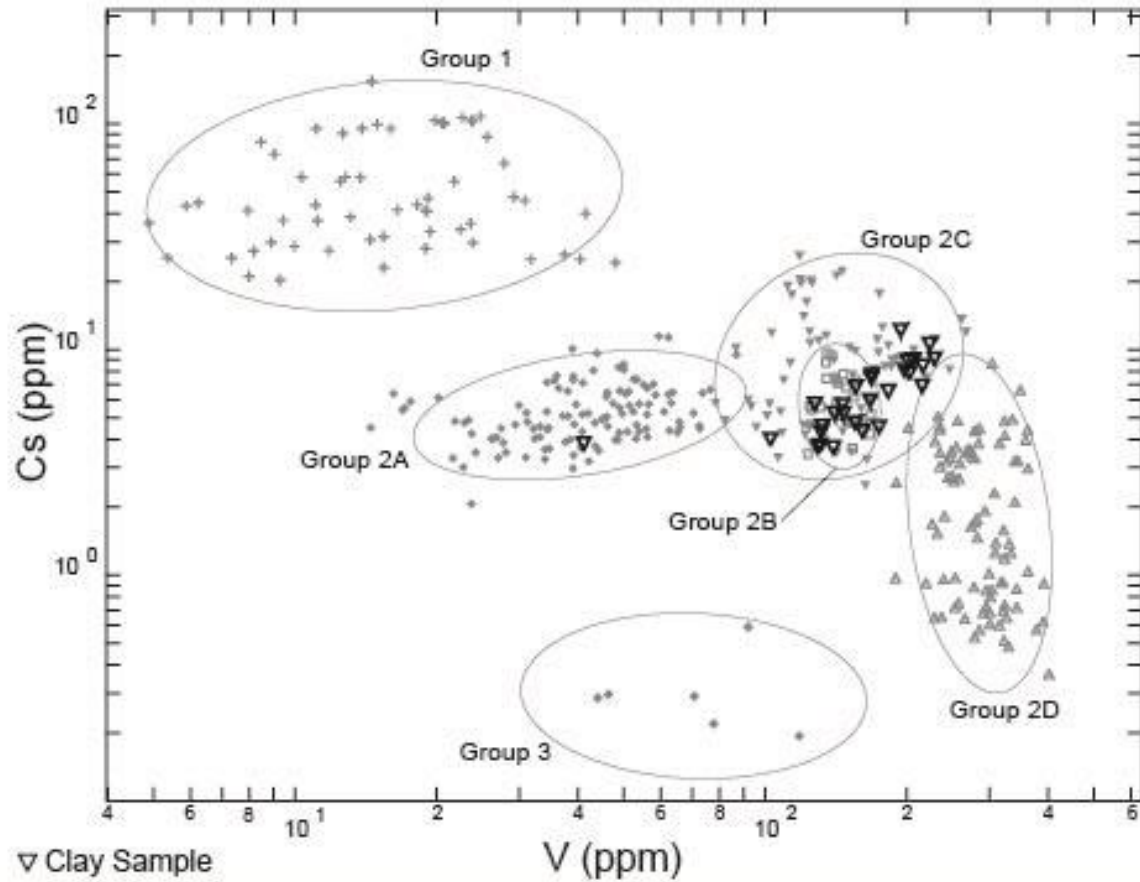

186 Several of the raw clays as well as the modeled ceramic compositions have very low
187 probabilities of belonging to any of the compositional groups we defined. Clays (and modeled
188 ceramics) from Ahteut and the lower Kobuk Valley are not strong statistical matches for any of
189 our groups, suggesting that these raw materials were likely not used for ceramic production.
190 Clays collected from Cape Espenberg have group-membership probabilities of effectively zero,
191 similarly indicating that they may not have been used prehistorically.

192

193 The ceramic-modeling results allow us to draw some preliminary conclusions regarding the
194 significance of our various compositional groups. Figure 6 shows the 11 different clay sources
195 projected against compositional groups, as well as the effects of adding 50% temper to each of
196 the clays (see also Table 7). In each instance, adding temper to raw clay results in compositions
197 more similar to those of ceramics placed within the Group 2 macrogroup, suggesting that some
198 of the chemical variation within the Group 2 subgroups is likely related to the kinds and
199 amounts of temper added to each product. Again, we note the dissimilarity of Group 1 and
200 Group 3 to any of the raw clays and to any of the modeled ceramics, suggesting that they were
201 produced using raw materials with fundamentally different chemical characteristics.

 217 circles), and modeled ceramic compositions with 50% temper (black circles). A: Cape Espenberg;
 218 B: Kotzebue Sound; C: Cape Krusenstern; D: Lower Kobuk; E: Ahteut; F: Onion Portage; G: Kobuk

219 Village; H: Mauneluk; I: Pah River; J: Shungnak; K: Imuruk Lake. Confidence ellipses are drawn
220 at the 90% confidence interval. Note that only two dimensions are shown here. Multivariate
221 probabilities for each raw clay and for modeled ceramic compositions are provided in the
222 Supplementary Material.

223

224 **6.0 Discussion**

225 *6.1 Clay Character*

226 The results of clay geochemical analysis indicate that clays across the region, more than
227 25,600,000 acres in size, are remarkably homogenous. This is surprising, given that samples
228 were collected from a variety of depositional contexts (e.g., glacial, lacustrine, colluvial). In
229 addition, processes of ceramic production (e.g., treatment of clay, addition of temper) and
230 postdepositional processes (e.g., weathering, leaching/enrichment of elements and minerals)
231 can alter the chemical composition of pottery so that the analytically determined compositions
232 of ceramic artifacts may not necessarily appear to be statistically strong matches to geological
233 clays. Analyses of clays and clay-rich sediments from the region suggest greater heterogeneity
234 in clays than indicated by the bulk geochemical analyses reported here. For example, analyses
235 of sediments associated with thermoluminescence-dated ceramics yielded variable
236 measurements for ^{238}U , ^{233}Th , and K (Feathers 2011). X-ray diffraction (XRD) of four clay
237 specimens (SLA 364, 369, 372, 389) from across the region indicates some variation in
238 mineralogical composition (Table 8) though additional analysis is needed (Perkins 2012). Illite,
239 chlorite, and albite tend to be enriched in Al, whereas dolomite and calcite are Ca-enriched. All
240 of the clay specimens subjected to XRD contain some amount of Al-rich feldspar (albite) and Al-
241 bearing phyllosilicate (illite), although the amount is undetermined at this time. INAA indicates
242 that all the sampled clays have approximately the same concentrations of Al, and XRD analysis
243 indicates that all the clays contain Al-bearing minerals. Thus, the XRD and INAA are in
244 congruence to some degree, although XRD analysis indicates greater heterogeneity in clay
245 composition than the INAA. XRD analysis of SLA 372 from the southern study area indicates that
246 clays in this region are somewhat enriched in Al. While Groups 1 and 2 ceramics show some
247 enrichment in Al, Group 3 ceramics are significantly depleted in Al; the results of XRD analysis
248 further indicate that the Group 3 ceramics may be nonlocal in origin. Additional mineralogical
249 analysis is necessary to test this hypothesis.

250

251 Table 8. XRD results for Four Clay Samples

| Clay Sample | Minerals identified | Study Region Sample Collected |
|-------------|---|-------------------------------|
| SLA 364 | Illite, plagioclase albite, chlorite | North |
| SLA 369 | Illite, chlorite, plagioclase albite, calcite, dolomite | Central |
| SLA 389 | Illite, chlorite, calcite, dolomite, plagioclase albite | Central |
| SLA 372 | Sanidine, chlorite, plagioclase albite, illite | South |

252

253 Ultimately, the analysis of clays proved to be of limited usefulness in linking ceramic
 254 geochemical groups to geological source areas at the fine scales as initially hoped; yet, the clay
 255 analyses do tell us something about production practices. The ceramic groupings identified in
 256 this study are based primarily on the paste recipes used by potters, which did have some
 257 regional variation based on the distribution of different geochemical groups across the region.
 258 Clay and temper modeling further support this conclusion, indicating that people did not
 259 frequently use the mineral material (typically beach or river sand) located adjacent to the clay
 260 sources to temper their ceramic materials. Rather, people may have taken advantage of the
 261 natural tempering of clay deposits and added little or no additional mineral temper to the
 262 ceramics. The geochemical similarity between the clays and the majority of the ceramics (those
 263 in Group 2c) suggests that little mineral material was added to clays. If mineral temper was
 264 added, modeling indicates that the mineral temper they included was not collected in proximity
 265 to the sampled clay deposits. Furthermore, the low group probabilities for modeled
 266 combinations of Cape Espenberg clays and tempers suggests that people were not procuring
 267 ceramic raw materials in this location. The absence of modeled compositions resembling Group
 268 1 or 3 suggests that ceramics from these groups may originate outside study area.

269

270 *6.2 Ceramic Production Regions*

271 Clay and ceramic geochemical analysis did identify several production regions. Most of
 272 the ceramic specimens fall into what we have referred to as Macrogroup 2 and its various
 273 subgroups. Group 2a samples were most common at central Kobuk and central Noatak sites
 274 (Ahteut and Maiyumerak, respectively), suggesting production in one or both of these locales
 275 and/or interaction between people living in these areas (Figure 7); there are several
 276 ethnographically known travel routes between the two river systems (Burch, 2005:282–285)

277 that may have been used in the past as well. Clay sample SLA 393 from the lower Kobuk is
 278 associated with this group, however, which makes it difficult to draw any more specific
 279 conclusions about the source locale of Group 2a. Group 2b is relatively rare and is most
 280 abundant in the vicinity of the Kotzebue site; thus, we suggest that ceramics in this group likely
 281 originated at or near Kotzebue. Group 2c ceramics are most abundant along the north coast and
 282 at central Kobuk river sites. These likely originated somewhere in the north-central region. In
 283 addition, because all of the clay samples except SLA 393 cluster within this group, Group 2c
 284 ceramics could represent unmodified use of regional clays. Group 2d ceramics are most
 285 abundant at southern sites and probably originated in this region.
 286

287
 288 Figure 7. Source group abundance in each sub-region of the study area.

289
 290 Group 1 and 3 ceramics are present in small numbers at several sites. At this point it is
 291 difficult to determine the origin of these ceramics with any certainty. Group 1 ceramics show
 292 significant enrichment in Ta. Deposits of Ta are reported on the Seward Peninsula and in the
 293 Kiana area of lower Kobuk (Swenson, 2012; Warner, 1985). Specimens assigned to Group 1 are

294 present at sites from both these regions, but they are proportionally most abundant in Lopp
295 Lagoon sites in the south. Group 1 is therefore tentatively assigned to the southern region,
296 though additional analyses may show that Group 1 materials originated outside the study area.
297 None of the modeled clay/temper samples are similar to Group 1, further suggesting that these
298 may have come from outside the Kotzebue Sound region. Group 3 comprises only five ceramic
299 specimens, and these too may have originated from outside the region. Group 3 specimens
300 were found at the Cape Krusenstern site complex (1 out of 50 specimens from the site) and the
301 Ambler Island site, located in the middle/upper Kobuk River (4 of 16 specimens from the site).
302 Given the relatively large Cape Krusenstern ceramic data set it seems unlikely that the rarity of
303 Group 3 ceramics is due to sampling issues at the site complex. None of the modeled
304 clay/temper samples are similar to Group 3.

305

306 **7.0 Conclusions**

307 Analysis of an expanded ceramic data set more firmly establishes the ceramic
308 geochemical groups identified by the pilot study (Anderson, et al. 2011). The original three
309 macrogroups (1-3), three subgroups of Macrogroup 2 (2a-2c), and Macrogroup 1 and 2 outliers
310 are now consolidated into three macrogroups (1-3), four subgroups of Macrogroup 2 (2a-2d),
311 and specimens that cannot be assigned to any of these macrogroups or subgroups. The addition
312 of clay and temper samples collected during a raw-material survey was informative, although
313 not in the manner anticipated. Though clay and tempering materials were collected over a
314 broad area, the clay specimens demonstrated remarkable geochemical homogeneity, as all but
315 one clay specimen groups with Macrogroup 2c. This suggests that potters added little to no
316 mineral temper to the clays and also that Macrogroup 2c ceramics were produced and
317 distributed from the north and central areas of northwest Alaska to the south. Group 1 and 3
318 ceramics might be evidence of pottery having been brought into the region from elsewhere.
319 Results suggest the possibility of areas of greater production (e.g., the central Kobuk River)
320 perhaps due to an abundance of clay or wood fuels for ceramic firing.

321

322 Overall, it is apparent that ceramics circulated widely around the region over time. This
323 work lays the foundation for further exploring the cultural processes that underlie these
324 distributions. A comparison of ceramic stylistic distribution patterns and geochemical groups is
325 forthcoming. Analysis of ceramic and raw material mineralogy will also further inform this

326 study. Ceramic petrography may be of particular use in refining our understanding of the nature
327 of inclusions present within ceramic sherds. This study of northern Alaskan ceramic production
328 locales provides insight into the complexities of hunter-gatherer ceramic production and
329 distribution.
330

Supplementary Information 1:

Discussion of the clay/temper modeling to simulate ceramic compositions

Using procedures outlined by Bishop and Neff (1989) and Neff et al. (1988, 1989) the various clay and temper specimens were combined to model compositions likely to be created through the combination of materials. Modeling was performed in R v. 3.1 (R Core Team, 2014) using the formula:

$$S_i = PT(T_i) + PC(C_i)$$

Where S_i is the elemental abundance in the modeled ceramic, T_i is the elemental abundance of the tempering agent, and C_i is the elemental abundance of the clay. PT and PC are the proportions of temper and clay, respectively, and must sum to one.

The probabilities of these modeled ceramic compositions belonging to the largest compositional groups used in this study are shown in Tables 1–16. Modeled compositions for the clay (SLA391) and temper specimen (SLA452) from the Middle Kobuk River/Ahteut region show consistently low probabilities of belonging to any compositional group. Though it must be noted that group membership probabilities show a consistent increase with the addition of more temper. Yet it seems unlikely that vessels comprised of more than 50% temper and less than 50% clay would realistically function.

Clay specimens (SLA368–371) from the Kotzebue/Cape Blossom area show reasonably high probabilities of belonging to Group 2c, and the mean elemental abundances of these four clays has a roughly 50% probability of group membership. However, the addition of specimen SLA435 as a tempering agent reduces the group membership probabilities to near zero. This likely relates to (1) the extreme concentration of Cr in temper specimen SLA435 (3523 ppm) relative to the clay specimens ($\mu = 156$ ppm), and (2) the relative enrichment of other transition metals in the temper specimen. Thus, the addition of even a slight amount of this temper to this clay results in a modeled ceramic composition outside the range of any compositional group used here. Using the second temper specimen from Kotzebue/Cape Blossom (SLA436) as a component in the modeling process results in ceramic compositions much closer to the composition of Group 2c, and group-membership probabilities for these simulated ceramic compositions peak around a temper proportion of 20%.

All of the simulated compositions of raw materials collected from Cape Espenberg have exceedingly low group-membership probabilities for all compositional groups presented here. This is particularly interesting given the relatively large sample of ceramics from Cape Espenberg in the current dataset.

Similar to the situation with the first specimen of temper from Cape Blossom, the raw clays from Imuruk Lake shows moderate probabilities of membership in Group 2c; however, the addition of specimens SLA437 and 438 as tempering agents serves to reduce these probabilities significantly.

Excepting specimens from the Lower Kobuk and Upper Kobuk, simulated ceramic compositions from the Middle Kobuk valley show consistently high group membership probabilities for Group 2c. This strongly suggests that potters were routinely collecting raw materials from within the central portion of the river catchment basin.

One interesting outcome of the clay and temper sampling is that none of the combinations of clay and temper produced a modeled ceramic composition remotely close to that of Group 1. Specifically, the highest concentrations of Ta observed in clay and temper specimens came from the Upper Kobuk River

40 (Pah River, Mauneluk River, and Shungnak River mouths). Yet the average abundance of Ta in these
41 specimens (≈ 1.08 ppm) is far less than that observed in Group 1 pottery ($\mu = 16.18$ ppm). Thus, Group 1
42 pottery represents a combination of raw materials consistently (and significantly) enriched in Ta relative
43 to anything documented in the widespread sampling of clays and tempering agents. A logical
44 conclusion, then, is that the Group 1 pottery could not have been made from any of the raw materials
45 sampled during the survey.
