ABSTRACT

Muscle samples from 105 marine mammals stranded along the Oregon-Washington coasts (2002-2009) were tested for levels of total mercury by Cold Vapor Atomic Fluorescence Spectrometry. The total mercury present is predominantly in the form of highly toxic methylmercury. After normalizing muscle tissue to 75% water weight, due to variance in water content, Steller sea lions (*Eumetopias jubatus*) and northern elephant seals (*Mirounga angustirostris*) exhibited the highest mean concentrations of total mercury followed by harbor seals (*Phoca vitulina*), harbor porpoises (*Phocoena phocoena*), and California sea lions (*Zalophus californianus*); 0.34 ± 0.278 , 0.34 ± 0.485 , 0.21 ± 0.216 , 0.17 ± 0.169 and 0.15 ± 0.126 mg/kg normalized weight, respectively. Mean normalized values demonstrated limited muscle methylmercury accumulation in these species in the Pacific Northwest. Normalizing muscle mercury concentrations eliminated variability from desiccation, and allowed for a clearer indication of the amount of mercury the animal accumulated before stranding. However, actual wet weight concentrations in some of the stranded carcasses were high enough to pose a risk to scavengers.

ACKNOWLEDGMENTS

I would like to thank everyone for his or her guidance in support of my project. I owe a large debt of gratitude to Stan Hillman and Ronald Jones for their extensive expertise, lab space, equipment, and friendship throughout the length of my research. For supplies and tools at a moment's notice, I'd like to thank Brad Buckley and Jason Podrabsky. Guidance in operating the CVAFS was provided by Dr. Liu and his lab at Florida International University. All of this would not have been possible if I did not have the support of my wonderful advisor, Deborah Duffield.

Chapter 1

Introduction

1.1 Project Rationale-

Mercury has recently gained recognition as a chemical of concern by the U.S. Environmental Protection Agency and the U.S. Food and Drug Administration (Gerstenberger *et al.*, 2009), partially due to advances in detection methods, but also from growing health concerns associated with heavy metal pollution. All across the United States, fish advisories have been put in place to notify consumers of the potential hazards of mercury in fish (U.S. EPA, 2001).

The last reported study of mercury in marine mammals from the Oregon coast is over thirty years old (Buhler *et al.*, 1974). This represents a serious gap in the knowledge of contaminants that are becoming increasingly common in federally protected marine mammals (U.S. EPA, 2001). Several marine mammal feeding and breeding areas are found on the Oregon and Washington coasts. Some species are here year round such as Steller sea lions (*Eumatopias jubatus*) and harbor seals (*Phoca vitulina*) (Merrick *et al.*, 1995; Pearson and Verts, 1970). Other marine mammals migrate into these waters seasonally, such as California sea lions (*Zalophus californianus*) northern elephant seals (*Mirounga angustirostris*) and to a more restricted extent harbor porpoises (*Phocoena phocoena*) (Calambokidis and Barlow, 1991; Reeves *et al.*, 2002).

Multiple advisories on mercury levels in fish have been put in place in Oregon (U.S. EPA, 2001), intended to limit human consumption of these fish. This raises questions about mercury accumulation in marine mammals whose diets are predominantly fish based. Humans limited to a few fish a month risk suffering neurological effects when mercury levels approach the parts-per-million range (Eisler, 2006; U.S. EPA, 2001). This could have dire consequences for marine mammals that primarily feed on fish from the same mercury-listed stocks. For humans, the Environmental Protection Agency has set a consumption advisory level at 0.5 ppm of mercury in fish; in contrast, the Food and Drug Association's consumption advisory level is 1.0 ppm within fish (Gerstenberger *et al.*, 2009), only further confusing individuals on which concentrations represent a health concern.

1.2 Mercury Sources

Mercury is distributed throughout the environment by both natural and anthropogenic activities (Eisler, 2006). Although Oregon does not have any significant point-source mercury pollution along the coast, there are several non-point source inputs from the burning of fossil fuels, volcanism, and historic mining operations (Manning, 2009; Park and Curtis, 1997; Nriagu and Becker, 2003; Sethejintanin *et al.*, 2004; Tunnicliffe *et al.*, 1996). In general, the largest contributor to mercury in the atmosphere comes from the burning of fossil fuels such as coal (Pacyna and Pacyna, 2002). Nearly 90% of the

mercury in the United States comes from solid waste incineration and fossil fuel combustion (Tang *et al.*, 2007). China, which brings a new coal burning power plant online each week, contributes 56% of the total global amount of mercury each year (Porcella, 1994).

Other less prominent sources of mercury include mining and cement production facilities. South of Eugene, OR, is the Black Butte Mine that is listed as an EPA Superfund site (Manning, 2009). The Black Butte Mine operated as a gold mine until the late 1960's. Gold was amalgamated with mercury, leaving mercury waste in large piles of mine tailings. This method of extracting gold was widely used before the consequences of mercury poisoning were known and understood. With building-sized piles of contaminated tailings, rain and erosion continually wash the mercury into surrounding streams, which then works its way to larger bodies of water such as the Willamette and the Columbia Rivers, entering the food chain in the process (Chasar *et al.*, 2009). Mercury is also released into the Willamette and Columbia Rivers from industrial activities along their banks, including the two dozen pulp and paper mills, two chlor-alkali production facilities, and various chemical manufacturing plants (Eisler, 1984).

Mercury also comes from volcanic eruptions. Fallout from the eruption of Mt. St. Helens in 1980 spewed nearly 100 tons of mercury into the surrounding area, as well as across the nation (Nriagu and Becker, 2003). In volcanic eruptions, mercury is released in two phases; first in the initial

eruption and second in the degassing period where the eruption is cooling, but still releasing gas. Ultimately, the released mercury enters waterways and finds its way into the food chain.

Hydrothermal vents are similar to volcanic eruptions. Tectonic activity from the sliding and grinding of the Pacific, North American, and Juan de Fuca plates cause hydrothermal vents off the coast of Oregon, Washington, and Alaska to release mercury several thousand feet underwater (Lamborg *et al.*, 2006). The fluids coming from hydrothermal vents on the Gorda Ridge contain an extremely elevated amount of mercury (5.8-17.3 ppm), when compared to the ambient mercury concentration of seawater (2-4 parts-per-trillion, ppt) (Lamborg *et al.*, 2006). Furthermore, it has been suggested that the Gorda Ridge could produce up to 4.0% of the total annual mercury inputs into the ocean (10-16.4 Mmole/year), (Lamborg *et al.*, 2006). The primary form of mercury released from hydrothermal vents is methylmercury, which settles in ocean sediments and is incorporated into benthic fauna (Lamborg *et al.*, 2006). Mercury is then concentrated by biomagnification, ending up in top predators such as marine mammals.

1.3 Mercury Transport & Speciation

Mercury is found in the environment in three forms: elemental, inorganic, and organic. Elemental mercury exists as mercury gas and metallic mercury (Hg^0), which is the form commonly used in dental amalgamations.

Mercury has two valence electrons, allowing it to easily volatilize, becoming mercuric mercury (Hg^{2+}) (Akagi and Nishimura, 1991). Mercuric mercury has a strong positive charge and in the atmosphere attracts negatively charged elements such as chlorine and sulfur (Morel *et al.*, 1998). Hg^{2+} bonds to form inorganic mercuric chloride (HgCl_2) and inorganic mercury sulfide, commonly called cinnabar (HgS). As inorganic mercury is formed in the atmosphere, it loses its volatility and deposits back in to soils and waterways (Morel *et al.*, 1998). In soils, lakes, streams, and oceans, sulfur-reducing bacteria use inorganic mercury for energy by cleaving the ionic bond between mercury and sulfur or chlorine (Jackson, 1998). Sulfur-reducing bacteria have vitamin B_{12} or cobalamin (Eisler, 2006), an organic compound with methyl groups, that replace the cleaved sulfur or chlorine ions to form organic mercury (CH_3Hg^+). Once mercury is converted into its organic form, it rapidly bioaccumulates (Eisler, 1984). Since methylmercury is not easily broken down and is not excreted from its host (Elhassani, 1983), it can concentrate in top predators to several magnitudes. Predators at the top of the food chain, such as marine mammals, bioaccumulate methylmercury $1:1 \times 10^6$ times greater than the dissolved mercury concentrations of the surrounding waters (U.S. EPA, 2001).

Mercury has no known metabolic function (Eisler, 2006). Forms of mercury that have low toxicity, such as inorganic mercury, can be transformed into forms with very high toxicity, such as methylmercury. Methylmercury is five

times more soluble than inorganic mercury (Goyer, 1986). Ninety to ninety-five percent of ingested methylmercury is absorbed in the GI tract compared with 15% of inorganic mercury (Goyer, 1986; Eisler, 2006).

Mercury acts as a mutagen, carcinogen, and teratogen causing genetic, histopathological, and embryological effects (Satoh, 1995). Methylmercury is the most toxicologically significant mercury species because it is produced naturally from inorganic mercury by microbial activity and is lipid soluble, allowing for easy transport across alveolar surfaces, as well as the blood-brain and placental barriers (Satoh, 1995). Ingestion is the main route of uptake for methylmercury and the primary target organs are the brain and neurological tissues. It specifically causes necrosis of the granule cell layer of the cerebellum, and is also associated with kidney disorders (Norton *et al.*, 1986). Sensory nerve fibers can be damaged, and membrane permeability of those cells increases upon mercury poisoning (Eisler, 2006). In the central nervous system, lesions developing in nervous tissue with degeneration of primary sensory ganglion cells (Roizin *et al.*, 1977) cause the effects of Mad Hatters Syndrome, the type of mercury poisoning found in felt hat makers (Norton *et al.*, 1986) and popularized by the movie *Alice in Wonderland*.

1.4 Mercury Analysis

As mercury has come under greater scrutiny in the last decade, analytical methods have improved, allowing rapid, inexpensive and more

accurate detection results. Mercury is now being detected in the parts-per-trillion (ppt) range for background levels usually found in drinking water. Using older methods that were based on atomic absorption, which measures the proportion of photons absorbed, does not allow such low detection limits or accuracy (Van Delft and Vos, 1988). The development of atomic fluorescence, which measures the proportion of photons emitted from mercury, has been responsible for the increase of sensitivity and accuracy of mercury detection (Jones *et al.*, 1997). In addition to detection sensitivity, previous methods for mercury detection in tissues used an open vessel digestion technique as well as cold vapor atomic absorption spectrometry. This open digestion allowed for a considerable loss of mercury to the surrounding air (Van Delft and Vos, 1988). Detection was improved by coupling a closed vessel technique with atomic fluorescence spectrometry. Detection limits went from 0.06 parts-per-billion (ppb) to 0.003 parts-per-trillion (ppt) (Szakacs, 1980). The closed vessel technique allows for rapid and cost effective analysis of multiple samples for total mercury and measures the sum total of all mercury species in a given sample (Jones *et al.*, 1997).

1.5 Mercury in Marine Mammals

In pinnipeds (sea lions and seals), the highest reported concentrations of mercury are found in their muscle, brain, blubber, kidney and liver tissues (Eisler, 2006). Mercury concentrations are especially pronounced in the liver

due to selenium complexation (Smith and Armstrong, 1978); therefore, total mercury concentrations are usually highest in livers of marine mammals, lower in muscle, and lowest in blubber (Brookens *et al.*, 2008).

Methylmercury does not break down in the body and deposits in vascular tissues such as muscle (Goyer, 1986). Muscle, unlike liver or blubber, does not metabolize methylmercury and it can concentrate to significant levels (Gaskin *et al.*, 1972; Holden, 1975; Harms *et al.*, 1978; Smith and Armstrong, 1978; Eisler 1984). Methylmercury in muscle tissue also concentrates with age.

Unlike muscle tissue, the liver has a low concentration of methylmercury, but a high concentration of other mercury species such as inorganic and elemental mercury. The liver as well as the kidney have multiple protective mechanisms against high concentrations of mercury, including metallothioneins and selenium. They are, therefore, unreliable indicators of toxicity (Goyer, 1986), while mercury in muscle tissue is 90-100% methylmercury primarily bound to muscle proteins (Buhler *et al.*, 1975). In general, the percentage of methylmercury is inversely correlated with total mercury content (Buhler *et al.*, 1975); (Fig. 1). If methylmercury is high, other mercury species such as inorganic and elemental mercury are low (as in muscle) or if inorganic and elemental mercury are high, methylmercury is low (as in liver).

Figure 1.1- The percentage of methylmercury is inversely related to the amount of inorganic and elemental mercury in tissue.

Marine mammals feed on a wide variety of prey, and thus, show varying levels of mercury accumulation (Reeves *et al.*, 2002). Species that feed on large fish and cephalopods contained up to ten times as much mercury as species that feed on small fish and crustaceans (Harms *et al.*, 1978). The accumulation of mercury has been shown to increase with age, reaching a plateau at 20 to 25 years of age in striped dolphins (*Stenella coeruleoalba*) (Itano *et al.*, 1984). Increased mercury concentrations have also been related to poor health due to diseases, such as leptospirosis, and to proximity to urban areas (Buhler *et al.*, 1975). Off the coast of Oregon and Washington increased mercury exposure comes from volcanic activity in the Juan De Fuca and Gorda Ridges (Lamborg *et al.*, 2006). China's increased use of coal burning power plants is also a main contributor to the overall amount of mercury that deposits on the west coast of the United States (Tang *et al.*, 2007), primarily

related to powerful trade winds (Kleypas and Yates, 2009). Superfund sites and industrial activities drain into major rivers such as the Columbia River and pollute coastal waters. Marine mammals feeding in these waterways act as environmental sentinels by bioaccumulating mercury. Because the last published mercury study was done in 1974 and was performed only on one species, it was important to look again at marine mammal mercury concentrations from Oregon.

1.6 Study Species

The Northern Oregon/Southern Washington Stranding Network (NOSWSN) has consistently collected data from marine mammal strandings since 1981. To evaluate mercury levels in these marine mammals, 105 muscle tissue samples were collected from the five most common strandings: Steller sea lions (*Eumetopias jubatus*, n=27), California sea lions (*Zalophus californianus*, n=31), northern elephant seals (*Mirounga angustirostris*, n=8), harbor seals (*Phoca vitulina*, n=18), and harbor porpoises (*Phocoena phocoena*, n=21)(see Appendix A).

Steller Sea Lions (Eumetopias jubatus)

Steller sea lions are the largest of the eared seals or Otariids. They are sexually dimorphic, with males reaching over a ton, and females reaching about half that, around 700 pounds (Reeves *et al.*, 2002). The coloration of

Steller sea lions is often light brown to dark brown ventrally. They have a very large body and head with a blunt snout. Pups are born with a dark pelage, and molt around four months of age to a lighter brown color.

Steller sea lions, also known as northern sea lions, inhabit the waters of the northern Pacific Ocean from California to the sea of Okhotsk, north of Japan. They are most abundant in the Gulf of Alaska and British Columbia (Le Boeuf *et al.*, 2007). Historically, Steller sea lions bred off of the Channel Islands in southern California, but they have not been seen there since the early 1980's (Fiscus and Baines, 1996).

In Oregon, Steller sea lions are found in breeding colonies on the Rogue and Orford Reefs, and they haul out consistently from Heceta Head to Astoria, feeding throughout Oregon waters. Females and males breed from late May until early July, giving birth to new pups a year later (Dempsey, 2010; Pitcher *et al.*, 2007). Steller sea lions strand on the Oregon/So. Washington coast throughout the year. Males will also swim up the Columbia River to the Bonneville Dam, taking advantage of local food sources such as salmon, steelhead, and sturgeon (Wright *et al.*, 2007). In the ocean, their main food source comes from walleye, herring, rockfish, cod, squid and octopus (Reeves *et al.*, 2002); all species that can be influenced by hydrothermal activity along the Oregon coast.

Of the three individual stocks: Western Pacific, Northeastern Pacific and Oregon, the Northeastern Pacific Steller sea lion stock has been declining

over the past 30 years (Pitcher *et al.*, 2007). The eastern stock of Steller sea lions is listed as a threatened species by the Endangered Species Act (Reeves *et al.*, 2002). Although, the cause is still uncertain, there is much speculation that pollution and over-fishing are the main drivers. It is estimated that the Oregon population of Steller sea lions is increasing every year with a current population of over 2000 animals (Oregon Sea Grant, 2003).

California Sea Lions (Zalophus californianus)

Another large otariid, California sea lions are dark brown to black, with females and juveniles light brown to yellowish. Adult males are easily distinguishable by their large sagittal crest. Female and juvenile California sea lions have a slender body, in contrast to adult males, which are large and robust throughout their entire body to their hind quarters, which is slender. The snout is long and straight. Pups molt at about five months in age to a light gray pelage (Reeves *et al.*, 2002). California sea lions are sexually dimorphic, with males reaching over 800 pounds and females usually only growing to around 200 pounds (Fiscus and Baines, 1966).

California sea lions breed off the southern California coast on the Channel Islands, and on more southern islands. Though their foraging range extends from the tip of Baja all of the way to Alaska, typically only males migrate into the northern waters, including Oregon and Washington (Reeves *et al.*, 2002). They have a breeding season that is very similar to the Steller

sea lion, typically forming rookeries from late May to early July (Fiscus and Baines, 1996). In the Pacific Northwest, their diet consists of anchovy, squid, sardines, mackerel and rockfish (Reeves *et al.*, 2002). In Oregon they have been seen opportunistically taking fish such as salmon and steelhead in the Columbia River up to the Bonneville Dam and in the Willamette River at the Willamette Falls (Wright *et al.*, 2007). These animals swim through and feed near major industrial centers and known mercury contaminated sites as well as in coastal waters (Sethajintanin, 2004).

They are seen in vast numbers throughout the Pacific Northwest. With a total population of 175,000-300,000, the actual number found off Oregon is unknown, but California sea lions on the lower Columbia River have been estimated at 1,200 (ODFW, 2003), and the numbers off Oregon and Washington have been steadily increasing.

Northern Elephant Seals (Mirounga angustirostris)

The northern elephant seal is the largest phocid pinniped in the northern hemisphere, with males reaching over two tons and females just over 1000 pounds at maximum weight (Le Boeuf *et al.*, 2000). Males are distinguishable from their immense size and inflatable proboscis. Just after molting, adults and juveniles are dark and become brown to tan over the next several months. Males can look extremely worn and mottled with a pink or light brown pelage, but are predominantly dark in color. Females are typically

dark brown with lighter colors ventrally. Pups are black at birth and molt to a silver color within a few months (Reeves *et al.*, 2002).

There are several northern elephant seals rookeries in California and Baja, but there are also two near the Oregon border at Cape Arago and Cape St. George. The only rookery north of Oregon is on Vancouver Island. During the winter months, northern elephant seals can be found at these sites, but the majority of their time is spent foraging. Northern elephant seals have one of the largest feeding ranges of any pinniped. They have been shown to forage from California to the Aleutian Islands, AK (Le Boeuf *et al.*, 2000). Their prey are typically deep water squid, skates, rays, and occasionally rockfish (Reeves *et al.*, 2002; Le Boeuf *et al.*, 2000). Elephant seals are deep diving mammals. They have been recorded to dive to depths of 5000 ft. (DeLong and Stewart, 2006), putting them in closer range of prey close to hydrothermal vents.

Adult male northern elephant seals are not commonly found in Northern Oregon/So. Washington; juveniles and weaner males and females primarily make up the documented strandings (Duffield, pers. comm.). The overall population of northern elephant seals is estimated at 150,000 (Reeves *et al.*, 2002).

Harbor Seal (Phoca vitulina richardsi)

Harbor seals are phocid pinnipeds that can be a wide variety of colorations from solid dark grey to mottled brown (Reeves *et al.*, 2002).

Harbor seals are medium sized phocids in which males can reach 350 pounds with females weighing a maximum of 280 pounds.

Harbor seals have a large worldwide distribution with multiple subspecies (Brookens *et al.*, 2008). The North Pacific harbor seal (*Phoca vitulina richardsi*) ranges from Baja, California, to the Aleutian Islands of Alaska (Reeves *et al.*, 2002), and are thought to be locally distributed in discrete subpopulations. Pacific harbor seal populations are found along the entire West Coast with several thousand seals living at the Channel Islands off of southern California and a population estimated at 16,000 between Oregon and Washington (Brookens *et al.*, 2008; NOAA, 2003). Harbor seals feed on small schooling fish, octopus, and squid. Pups will forage for slow moving shrimp and switch to faster moving capelin as their swimming skills improve (Reeves *et al.*, 2002).

Harbor seal populations are estimated at 300,000 to 500,000 worldwide (Sea World, 2005). In the Gulf of Alaska, harbor seal populations declined in the 1970's and 1980's due to commercial trawl fisheries. In the Pacific Northwest, harbor seals are also exposed to pressure from commercial and recreational fisheries.

Harbor Porpoise (Phocoena phocoena)

The only cetacean (whales and dolphins) in this study, the harbor porpoise is a small, fuselage-shaped animal. Males are typically smaller than females and can reach 130 pounds (Harms *et al.*, 1997). Females are slightly larger and can reach 160 pounds as an adult. Their coloration is usually gray dorsally, with lighter sides and belly. They have a triangular dorsal fin that is dark grey, as are the color of its flippers (Reeves *et al.*, 2002).

Harbor porpoises are found only in the northern hemisphere and, as their name implies, are coastal, found in fjords, bays, estuaries, and harbors (Reeves *et al.*, 2002). The Pacific population has a large range from Monterey Bay all the way north to the Chukchi Sea, including the Aleutian Islands of Alaska (Reeves *et al.*, 2002). Six stocks of harbor porpoises have been identified on the West Coast of the United States (Chivers *et al.*, 2002), with a stock specific to the Oregon/Washington coast (Laake *et al.*, 1998). Harbor porpoises feed on schooling fish, herring, squid, and octopus (Reeves *et al.*, 2002).

Little is known about harbor porpoise ecology. Groups of 10 to 100 animals have been seen feeding together (Read, 1981). In the Oregon Stranding Network area, harbor porpoises are known to seasonally move along the Oregon coast, probably associated with feeding. The Oregon/Washington harbor porpoise population is estimated at 11,599 animals (Laake *et al.*, 1998). Although populations in the northwest Pacific

are considered stable, a threat exists from commercial fisheries using gillnets (Reeves *et al.*, 2002).

1.7 Current Study

There is a paucity of literature on mercury in marine mammals from Oregon. The only previous published study of mercury in marine mammal muscle tissue was done by Buhler *et al.* (1974) on California sea lions (0.84-1.64 ppm ww). Since mercury pollution is primarily related to the combustion of fossil fuels, human population size should have an indirect effect by increasing the availability of pollutants to the environment. The human population in Oregon has nearly doubled since 1970, and one would predict this to significantly increase the amount of mercury found in rivers and oceans. Furthermore, trade winds from China deposit mercury from coal burning power plants into the waterways and soils (Tang *et al.*, 2007; Kleypas and Yates, 2009), and this source of mercury increases every week with the continuous addition of new coal burning power plants. This study is designed to investigate whether mercury concentrations in muscle tissue have increased since the previous study in Oregon due to prolonged and higher levels of exposure. I am also testing whether mercury in muscle will increase with the age of the animal, reflecting accumulation over time, and whether there are differences in bioaccumulation between males and females.

The results of this study have been accepted for publication in
Marine Mammal Science. The accepted manuscript is presented in Chapter 2.

Chapter 2

Marine Mammal Science Journal Publication¹

2.1 Introduction

Mercury contamination of marine mammals on the west coast of the United States can come from multiple sources including mine tailings, hydrothermal vents, municipal wastes and trade winds which carry volatilized mercury across the Pacific Ocean from Asia (Klangsin and Harding 1998, Lamborg *et al.* 2006, Tang *et al.* 2007, Manning 2009). Several areas in California and throughout the northern Pacific have well documented mercury contamination in coastal waterways (Beckmen *et al.* 2002, Brookens *et al.* 2008). Major metropolitan areas such as Portland, OR and Vancouver, WA border the Columbia River that empties into the Pacific Ocean. The Portland Harbor Superfund site located along the Willamette Fork of the Columbia River has been shown to contain fish with mercury concentrations of up to 0.520 mg/kg ww (Sethajintanin *et al.* 2004). Further upriver from the Willamette Fork of the Columbia is the NPL Superfund site, the Black Butte mine (www.epa.gov), which leaches mercury into the Coast Fork Willamette River. Mean fish fillet mercury concentrations from the Coast Fork (0.66 mg/kg ww) are higher than concentrations at the EPA designated site downstream (Hope and Rubin 2005). A national monitoring study (1969-

¹ Wintle, Nathan J.P., Duffield, Deborah A., Barros, Nélío B., Jones, Ronald D., Rice, James M. Total Mercury in Stranded Marine Mammals from the Oregon and Southern Washington Coasts. *Marine Mammal Science* Accepted for publication November 2010.

1991) of whole freshwater fish revealed that the highest mercury concentrations (0.33-1.7 mg/kg ww), were found in northern squawfish (*Ptychocheilus oregonensis*) from the Columbia River basin (Henderson and Shanks 1973, Lowe *et al.* 1985). Few studies have investigated mercury pollution of Oregon coastal waters, largely due to the fact that Oregon has no large mercury point source situated near the coast (Park and Curtis 1997).

Steller sea lions (*Eumetopias jubatus*), California sea lions (*Zalophus californianus*), and harbor seals (*Phoca vitulina*) in particular frequent these polluted waterways as well as the coastal areas, and are at risk of accumulating harmful concentrations of mercury. This has been proposed as a factor in the recent decline of Steller sea lions from the Prince William Sound and Southeast Alaska where mean levels of mercury in their hair was found to be 2.74 mg/kg ww (Beckmen *et al.* 2002). Marine mammal species are extremely susceptible to mercury contamination from both natural and anthropogenic inputs (Eisler 2006), especially as marine mammals are located near or at the top of the food chain, making them effective bioindicators of mercury contamination (Chasar *et al.* 2009). The last study of mercury contamination in the muscle tissue of marine mammals from the Oregon coast is nearly three decades old (Buhler *et al.* 1975), highlighting the need for updated research on heavy metal contamination in these species.

Analyzing muscle tissue for mercury is toxicologically significant because unlike liver and kidney, muscle does not have the ability to form

soluble complexes with cysteine or glutathione or produce metallothioneins, which can cleave the carbon-mercury bond and reduce monomethylmercury (CH_3Hg^+) into inorganic Hg (Goyer 1986). Furthermore, total mercury burden has been shown to be highest in muscle tissue, over both the liver and kidney, and is recommended for biomonitoring (Brookens 2008). Though mercury concentrations are pronounced in the liver (Anas 1974), most of this mercury is biologically unavailable due to selenium complexation (Smith and Armstrong 1978). Using total mercury (THg) in muscle tissue has the added benefit that it is almost entirely in the form of CH_3Hg^+ (Gaskin *et al.* 1972). Monomethylmercury, in comparison to all other Hg species, readily crosses biological barriers such as the GI tract and deposits in vascular tissues (Elhassani 1983), establishing muscle as a toxicologically significant tissue.

Given the uncertainty of mercury exposure and accumulation in marine mammal species along the coasts of Oregon and southern Washington, we have determined THg in five species representing different foraging and habitat ranges using muscle samples available from the Oregon and southern Washington stranding networks. This study is the first to examine multiple species from the Oregon coast.

Materials and methods

2.2 Sample collection

Muscle samples from 105 marine mammals: 31 California sea lions (29 male, 1 female, 1 unknown), 27 Steller sea lions (10 male, 17 female), 21 harbor porpoises (*Phocoena phocoena*) (12 male, 7 female, 2 unknown), 18 harbor seals (8 male, 9 female, 1 unknown), and 8 elephant seals (*Mirounga angustirostris*) (6 male, 2 female), were obtained from necropsies of stranded animals along the Oregon and southern Washington coasts from 2002-2009 (Fig. 1). Muscle tissue was removed from the dorso-lateral or ventral subscapular region, immediately bagged and placed on ice. Samples were stored at -20°C until analyzed. Morphological data including sex, length, decomposition code, and gross findings were recorded during the necropsy. The majority of the stranded animals were from northern Oregon between Cannon Beach and Astoria, $n = 75$. The remaining strandings were from Long Beach, WA or along central Oregon to Bandon, $n = 21$ and 9, respectively. Two California sea lion samples were from animals that died near the Columbia Fork on the Willamette River (see Appendix A).

Fig. 2.1- Locations of strandings sampled from Oregon and Washington, 2002-2009. Value next to city name indicates number sampled.

2.3 Chemical analysis

Muscle tissue was digested in 10mL glass ampules with 2mL HNO₃ and 1mL of H₂O following the closed-ampule digestion procedure described by Jones *et al.* (1997), and mercury levels were determined by Cold Vapor Atomic Fluorescence Spectrometry. All Hg analyses were performed on a

10.025 Millennium Merlin Hg analyzer from PS Analytical (Deerfield Beach, FL). In this analysis the digested tissue sample reacts with stannous chloride to convert Hg^{2+} from the samples into Hg^0 . The converted mercury is taken out of solution in a gas liquid separator by argon and detected by a fluorometer fixed at 254 nm.

2.4 Quality control

Quality control followed the method established by Jones et al. (1997). A stock mercury reference standard (100mL Hg, Fisher Scientific) was used to prepare a calibration curve for each sample set. The method blank (1% HCl), and a 5.0 mg/kg spike were injected into an ampule prior to nitric acid digestion for the last set. The recovery rates for both the blank and the spike were within the acceptable EPA range at 0.0% and 2.6% difference, respectively. Roughly 5% of the samples were run as duplicates, with a relative percentage difference of 33%. During operation, each sample was run twice and averaged.

2.5 Data analysis

The degree of decomposition of tissues from individual stranded marine mammals varied greatly, leading to variability in the amount of water in each sample. To correct for this variance in percentage water, a 0.5 g plug from each tissue sample was desiccated in a vacuum centrifuge (SC210A

Speedvac plus) for 12 hrs to determine dry weight. The range of tissue water weight among samples was 29.4-73.9%. Given the considerable range of percentage water seen among the stranded samples, the detected THg wet weight values for each animal were normalized by re-calculating individual levels based on a standard muscle water content of 75% (Skelton 1925). Normalized values were calculated by comparing wet and dry weights for each sample to determine % water content and using this % in the following formula: $[\text{mg/kg of THg before desiccation}] (\% \text{ water loss}) = [\text{normalized mg/kg}] (0.75)$. Normalized values were used in the statistical analyses.

2.6 Statistics

A Shapiro-Wilk test for normality was run on the normalized values. Since these values were not normally distributed, all values were log transformed for further statistical analysis. Log transformed data for all species with the exception of Steller sea lions, also failed the Shapiro-Wilk test for normality. Therefore a parametric statistic (t-test) was used to test THg between sexes for Steller sea lions, but all other species were analyzed using the non-parametric Wilcoxon test. Linear regression was performed to look for an association of THg with length (an estimate of age). To test for significance among age classes within each species, the Kruskal-Wallis non-parametric test was run on each species except Steller sea lions, in which a one-way ANOVA was used to test for significance. All statistical analyses

were run using SPSS statistical software (version 18.0.), with a significance level of (0.05).

2.7 Results

Of the five species examined, the highest mean concentrations of normalized THg were found in Steller sea lions and northern elephant seals, followed by harbor seals, harbor porpoises and California sea lions (Table 1; Appendix B). The distribution of individual values per species were skewed; therefore, species THg concentrations are given both as means and medians. Individual levels of normalized THg ranged from 0.00-1.50 mg/kg.

There were no significant differences in normalized THg between sexes in any of the species examined (although only one female California sea lion was tested). While there was a trend of increasing mean normalized wet weight with age cohort (Table 2), the differences between age cohorts were not statistically significant. We found no significant correlation between length and normalized THg concentrations for all species.

2.8 Discussion

We report here findings on total mercury concentration from muscle tissue in Pacific Northwest marine mammals. For the five species that we tested, the reported mean and median normalized wet weight values and ranges indicate varying degrees of THg accumulation in marine mammals off

the Oregon and southern Washington coasts. Steller sea lions and elephant seals had the highest mean values, but overall, normalized THg values ranged from 0.00-1.50 mg/kg (ppm) with the highest concentration noted in an adult elephant seal (Table 2.1).

Although numerous studies exist on mercury in marine mammals, few have reported THg concentrations from muscle tissue, which does not readily demethylate monomethylmercury and is the best overall indicator of accumulation (Buhler *et al.* 1975, Mieiro *et al.* 2009). Table 3 summarizes reported muscle THg concentrations for four of the five species we studied. Steller sea lions and northern elephant seals exhibited a normalized mean concentration of 0.34 mg/kg THg in our study. Previous studies from the Aleutian Islands, AK reported a single Steller sea lion with a muscle concentration of 1.65 mg/kg ww (Beckmen *et al.* 2002) and females, pups and males with muscle concentrations of 0.15, 0.22 and 0.26 mean mg/kg ww, respectively (Holmes *et al.* 2008). No previous mercury levels were available for Steller sea lions from Oregon, Washington or California waters. This is the first report for northern elephant seal THg concentrations in muscle. The previously reported muscle concentrations for harbor seals from central California and Eastern Canada were 0.75 and 0.71 mg/kg THg ww mean and mg/kg THg ww, respectively (Sergeant and Armstrong 1973, Brookens *et al.* 2008). For harbor seals our normalized mean concentration (0.21 mg/kg

normalized ww) was considerably lower than either of these reported mean concentrations. No harbor porpoise mercury levels have previously been reported for the Pacific coast of the United States; however, mean muscle concentrations from the northern Atlantic and adjacent waters, and the Black Sea of eastern Europe were found to range from 0.3 to 2.1 mg/kg THg fw or ww (see Table 2.3). Our normalized harbor porpoise concentrations from the Pacific Northwest were also considerably lower than all previous studies (0.17 mg/kg normalized ww). Similarly, the normalized muscle THg values for California sea lions evaluated in Oregon and southern Washington in this current study were lower than previously reported values for central Oregon

(0.15 mg/kg normalized ww vs. 1.64 mean mg/kg THg ww; Buhler *et al.* 1975).

current study were lower than previously reported values for central Oregon (0.15 mg/kg normalized ww vs. 1.64 mean mg/kg THg ww; Buhler *et al.* 1975).

A complication arose in the comparison of concentrations among studies related to the condition of muscle at the time of sampling. The muscle water content of the stranded animals in our study varied from 29% to 74% depending on the condition of the animal at the time of stranding. This difference in water content could give a false sense of THg accumulation and normalizing the wet weight allowed for a clearer indication of the amount of mercury the animal accumulated before stranding, facilitating comparisons between fresh tissue samples from a healthy animal and decomposed tissues from a stranded animal. Compensating for this by normalizing our wet weights to a standard vertebrate 75% muscle water content lowered the mean, median and range concentrations for all species when compared to the unnormalized wet/dry weight values (see Table 2.1). In looking at reported concentrations for these species, it was not always clear whether the samples were from freshly dead and non-dehydrated animals. It was therefore hard to evaluate whether the higher concentrations previously reported in harbor seals, harbor porpoises and California sea lions were affected by water loss or reflective of regional differences. On the other hand, wet weight (non-normalized) would be of more importance for predators feeding on these carcasses on the beach. We have observed seagulls, crows and eagles feeding

on carcasses in the Northern Oregon/Southern Washington stranding region and it is the higher mean wet weight concentrations (Table 2.1) that closer reflect their risk of bioaccumulation.

Previous studies by Gaskin *et al.* (1972), Harms *et al.* (1978), Smith and Armstrong (1978), and Eisler (1984), reported that total mercury values increased with length (*i.e.*, age). The concentrations they found were reported either as fresh weight or wet weight. After normalizing our data, we found no significant correlation between length and THg concentration for all species. When evaluated as age cohorts (Table 2.2), although there was a trend towards higher mean concentrations with age cohort, there was no statistical correlation between age and THg concentration.

Steller sea lions and northern elephant seals exhibited the highest concentrations of mercury in our study. It is not clear at this point whether exposure to and accumulation of mercury in these species is due to geographic range or prey choice. Both of these species move long distances in search of food along the west coast of the United States but prey upon different species with the northern elephant seal foraging further from shore (Brillinger and Stewart 1998, Pitcher *et al.* 2007). Harbor porpoises, which feed on a wide variety of pelagic and demersal prey, are also highly mobile with large home ranges (Reeves *et al.*, 2002 *et al.* 2002), but had notably lower Hg levels. Harbor seals, thought to have more localized foraging ranges, closely matched levels found in the harbor porpoises, while California sea lions, which are

highly mobile (Zuerner *et al.* 2009), also showed low levels of mercury accumulation.

2.9 Conclusions

Despite the recent increase in awareness of the hazards of mercury contamination, very little has been done to curtail its input into the ecosystem in Oregon and Washington (Seigneur *et al.* 2004, Harper and Harris 2008). For example, one such input comes from mine tailings at the head waters of the Willamette River, abandoned during the 1960's (Manning 2009), which are still leaching mercury into the environment (Chen *et al.* 2008). Furthermore, although few data exist on the prevalence of non-point source mercury pollution, such as that from the burning of fossil fuels, it is estimated that coal-burning in China is responsible for 21% of the total mercury deposition in the United States (Tang *et al.* 2007). Another possible source of mercury comes from natural sources such as hydrothermal vents near the Gorda Ridge off the coast of Oregon (Lamborg *et al.* 2006) and volcanic eruptions such as the Mt. St. Helens eruption of 1980 that spewed 97.7 metric tons of mercury into the atmosphere and surrounding area (Nriagu and Becker 2003). Concentrations of THg in muscle from the coastal Oregon and southern Washington marine mammal species reported here indicate limited accumulation. However, the significance of these findings depends on whether one is concerned about levels reflecting relative accumulation within

these species (0.00-1.50 mg/kg normalized ww) or upon the impact for scavengers feeding on the stranded carcasses (0.00-4.13 mg/kg ww). We emphasize that muscle water content in dead marine mammals that have been on the beach for varying periods of time can inflate (often considerably) the apparent muscle wet weight values. It is apparent that mercury accumulation is not localized to highly populated areas, but is dispersed along the northwest coast and presumably transported by prevailing winds and from waterways such as the Columbia River (Tang *et al.* 2007, Brigham *et al.* 2009). Given this preliminary look at THg in marine mammals in the Pacific Northwest, we emphasize the need for closer monitoring of mercury loads in these species in order to more accurately track mercury trends over time. As more interest develops over reintroduction of key scavengers such as condors into the Northwest region (California Condor Recovery Program), the levels of mercury found in marine mammal carcasses along the coast becomes a very real concern.

Chapter 3

Discussion

3.1 Marine Mammal Distribution

Environmental mercury concentrations should be highest where there is a large input from human beings (Eisler, 2006, Tang *et al.*, 2007, U.S. EPA, 2001), implying that the more time the animal spends near highly populated regions, the more mercury it should have. But in Oregon, there are also significant natural sources of mercury from hydrothermal vents. The Northern Oregon Marine Mammal Stranding Network responds to strandings of both year-round species such as Steller sea lions and harbor seals, and also to seasonal species such as California sea lions, elephant seals and harbor porpoises. Since, the primary route of THg accumulation in marine mammals would be from feeding on mercury contaminated prey (Eisler, 2006), prey near hydrothermal vents could be especially vulnerable to mercury accumulation up the food chain. Therefore, animals living around these tectonic areas will be exposed mercury more often than seasonal migrants into the region. Differences in diet could also be a major determinant of accumulated mercury levels. Hydrothermal vents off of the Oregon coast emit a large amount of mercury which bioaccumulates up the food chain and large fish and cephalopods contain higher levels of mercury than small schooling fish and crustaceans (Harms *et al.*, 1978).

Total mercury concentrations reflected each of the five species' diets and distribution (Reeves et al., 2002). The main corollary to THg mean concentration seemed to be individual species' distribution. For example, Steller sea lions exhibited the highest mean total mercury concentration. They breed off the southern Oregon coast and are found along the Oregon/Washington coast year round. California sea lions exhibited the lowest mean THg concentration, and only seasonally forage in Oregon. Northern elephant seals also exhibited higher levels of THg concentrations, and have rookeries that are established on the southern Oregon coast. In addition, these are the deepest diving, northern hemisphere pinniped and being able to feed on deeper prey may also be an important factor to mercury exposure. Harbor porpoises (with lower mean THg levels like California sea lions) are found more frequently stranded from late spring to early fall and may be more seasonal in Oregon/Washington waters following schooling fish, such as anchovies, sardines and herring.

Tectonic activity is a primary demographic cause for elevated total mercury concentrations (Tunnicliffe *et al.*, 1996, Lamborg *et al.*, 2006). Particularly in southern Oregon and along the Oregon coast, the plate boundaries between the Pacific Plate, the Juan de Fuca Plate, and the North American Plate are high in tectonic activity and give rise to hydrothermal vents (Lamborg *et al.* 2006). This activity is part of the "Ring of Fire", which circles the entire Pacific Ocean (Tupper *et al.* 2004). At these plate

boundaries large amounts of methylmercury are released into the surrounding sediments and organisms at concentrations up to 5.8-17.3 ppm (Lamborg *et al.*, 2006). Methylmercury is taken up by benthic fauna and squid and then bioaccumulated up through the marine food web (Reeves *et al.*, 2002; Chen *et al.*, 2008). Although, most of the mercury is deposited onto the seafloor, these vents can disperse their plumes up to 2000 meters into the water column (Baker *et al.*, 1995). These vents are often too deep for most marine mammals to reach, even at their greatest recorded diving depths (Reeves *et al.*, 2002). However, the hydrothermal vents on the Juan de Fuca Ridge are anywhere from 1500 to 2600 meters deep and with plumes that can extend 2000 meters to the surface (Lucas 1972); this brings the direct source of mercury into the range of prey on which coastal marine mammals are foraging.

A second variable that may be important in explaining the observed mercury levels relates to trade winds and Pacific Gyre movements which bring mercury pollutants to the west coast of the United States from China. This source of mercury first affects the Aleutian Islands of Alaska and then is moved several thousand miles south along the west coast of the United States to California (Kleypas and Yates, 2009). Because the distance that the wind and water must travel before reaching Alaska is considerably less than the distance to California (Kleypas and Yates 2009), a higher concentration of mercury is deposited in the waters of Alaska compared to Californian waters

(Tang *et al.* 2007). The species with a more northern range (particularly Steller sea lions and northern elephant seals) exhibit higher mean levels of mercury than the more locally distributed or southern species (harbor seal, harbor porpoise and California sea lion; Table 2.1).

3.2 Interpreting THg Data

Analyzing tissue as dry weight requires desiccating the tissue being analyzed in order to quantify the percentage water present in the collected wet weight sample. Although the wet weight sample provides an estimate of the THg (mg/kg) present in a carcass on the beach, reporting THg concentrations as dry weight has the advantage of being comparable. When sampling was limited to beach-cast animals, I found that the water content of the muscle varied considerably from individual to individual (Table 3.1). This was due

Table 3.1-Percent water weight $\pm$ S.D., range in parenthesis. The variation in % H₂O could be due to a large number of factors including sickness at stranding, time on beach or time in storage.

Species	n	% H ₂ O mean $\pm$ S.D. (range)
Steller sea lion	27	43.9 $\pm$ 8.5 (29.4 - 67.5)
N. Elephant seal	8	49.1 $\pm$ 11.6 (37.6 - 73.9)
Harbor seal	18	44.4 $\pm$ 8.2 (35.2 - 58.4)
Harbor porpoise	21	44.5 $\pm$ 7.8 (32.3 - 64.3)
CA sea lion	31	46.4 $\pm$ 8.2 (33.9 - 65.4)

to a combination of factors, including loss of water in decomposing carcasses, illness and dehydration in the animal which had caused it to strand, or simply water loss on subsequent tissue storage. Mercury analyses reported as THg concentrations dry weight remove this bias and allow inter-individual and inter-species comparisons.

These dry weight values can be normalized to a muscle water percent (here chosen to be 75% water; Skelton, 1925) for comparison with literature values taken on fresh animals. In this study these normalized values were used to compare mercury values in the literature to mercury values in the studied species (see Chapter 2).

A caveat to this is that mercury levels being bioaccumulated from dead marine mammal carcasses by scavengers such as gulls, ravens, eagles and coyotes (as observed by NOSWSN) are based on the wet weight of the tissues ingested. Given the range of water loss in stranded marine mammal muscle (Table 3.1), the actual exposure level to THg (mg/kg ww) can be much higher than the normalized values I report for comparative purposes (Appendices B,C,D).

Steller Sea Lions vs. California Sea lions – wet weight THg levels

In Oregon, Steller sea lions are often seen with California sea lions. Both species are also seen up the Columbia River taking salmon and sturgeon (Wright *et al.*, 2007), and along the Oregon coast on jetties and rocky

outcrops. These two species have overlapping ranges in Oregon and Washington and overlapping prey choices (Reeves *et al.*, 2002), but were significantly different when analyzed for THg concentrations. Steller sea lions had the highest mean wet weight concentration of THg (1.24 ppm ww) and California sea lions had the lowest (0.54 ppm ww).

Steller sea lion home ranges extend from southern Oregon to the Aleutian Islands of Alaska. Resident Steller sea lions have established rookeries in southern Oregon with a steadily increasing population of over 2000 (Oregon Sea Grant, 2003). Steller sea lions feed on a wide variety of prey including sturgeon, steelhead, rockfish, walleye, herring, cod, squid and octopus. In southern Oregon particularly, these prey come from the areas exposed to mercury-contaminated hydrothermal vents (Tunnickliffe, 1986). The length of time per year that Steller sea lions spend feeding in mercury polluted waters is possibly far greater than California sea lions which feed in these same areas only six to seven months of the year and have the more southern distribution of the two species (Van Dover, 2010). The reason we are seeing differences in mercury concentration may simply be due to the time that these two species spend feeding in contaminated areas.

Northern Elephant Seals - wet weight THg levels

Northern elephant seals contained the second highest mean wet weight concentration of total mercury in this study (0.94 ppm ww). Elephant seals

swim and feed in tectonically active waters off the Oregon coast (Le Boeuf *et al.*, 2000). The breeding grounds for elephant seals are off the southern California coast on the Channel Islands and also in the San Francisco Bay area (Le Boeuf *et al.*, 2000). Though they do not breed as far north as Steller sea lions, they have recently established rookeries in southern Oregon. In the non-breeding season, they range as far north as the Aleutian Islands of Alaska, generally feeding on deeper prey such as squid, skates, rays and more coastally, rockfish. Swimming in areas as far north as the Alaskan Gulf would put elephant seals in waters that are tectonically active as well as polluted by trade winds and the Pacific Gyre similar to Steller sea lions (Kleypas and Yates, 2009). Northern elephant seals are one of the deepest diving of the pinniped species, staying over an hour at depths of up to 5000 ft. (Reeves *et al.*, 2002). At this depth, they could indeed be feeding on the highly contaminated benthic fauna near hydrothermal vents.

Harbor Seals and Harbor Porpoises - wet weight THg levels

Total mean mercury wet weight concentrations for harbor seals were 0.71 ppm ww, while harbor porpoises were slightly less at 0.56 ppm ww. Both the harbor seal and harbor porpoise are smaller marine mammals that feed on migrating schooling fish, as well as squid (Brookens *et al.* 2008; Joiris *et al.* 2001). Harbor seals, with a slightly higher mean THg wet weight concentration, can be found in Oregon all year long while the harbor porpoise,

which had a lower mean THg concentration, seems to seasonally move throughout Oregon waters (Lamborg *et al.* 2006). Harbor porpoises are also commonly found off Oregon during the calving season. The higher concentration of total mercury in harbor seals versus harbor porpoises may reflect both annual geographical distribution and differences in preferred prey distribution. Both species are less exposed to mercury pollution than Steller sea lions and northern elephant seals.

3.3 Conclusion

I had hypothesized that exposure of Pacific Northwest marine mammals to mercury would have increased since the previous study of Buhler *et al.* (1975). They reported mean THg concentrations of 0.84 -1.64 ppm ww in California sea lions from the central Oregon coast. In my sampling of California sea lions from central to northern Oregon, I found a mean of 0.54 ppm ww. The level in California sea lions had not appreciably increased, and had in fact significantly decreased. There were no comparable levels available for the rest of the species studied in Oregon.

Also, previous studies on mercury (Gaskin *et al.*, 1972; Holden, 1975; Harms *et al.*, 1978; Smith and Armstrong, 1978; Eisler, 1984) showed that the age of the animal was in direct relation to the amount of mercury they had accumulated. I saw a similar result for Steller sea lion dry weight and wet weight ($p=.025$ and $p=.042$, respectively), harbor seal dry weight ($p=.050$),

and harbor porpoise dry weight and wet weight ($p=.004$ and $.045$, respectively; Table 3.2 and Chapter 2; Appendix E). Elephant seals and California sea lions did not exhibit statistically significant changes within mercury concentration with respect to age. Total mercury was not significantly correlated with the health status of the stranded animal in any of the species (Appendix F).

Table 3.2- All three methods for reporting mercury concentrations were analyzed for significance between THg and the age of the animal. Significance level of 0.05. A significant value is indicated by bold.

Species	Dry wt.	Wet wt.	Norm wt.
Ej	$r^2=.312, p=.025$	$r^2=.214, p=.042$	$r^2=.142, p=.094$
Ma	$r^2=.005, p=.883$	$r^2=.000, p=.980$	$r^2=.027, p=.725$
Pv	$r^2=.210, p=.050$	$r^2=.203, p=.061$	$r^2=.158, p=.102$
Pp	$r^2=.379, p=.004$	$r^2=.238, p=.045$	$r^2=.145, p=.101$
Zc	$r^2=.057, p=.196$	$r^2=.046, p=.246$	$r^2=.042, p=.269$

Mercury is found worldwide, from the deepest trenches in the ocean to the highest mountaintops. Although mercury is classified as a heavy metal, it

can take the form of a gas, a liquid, or a solid. The amount of mercury that enters the environment as a direct consequence of human activity is significantly less than the amount coming from natural processes such as hydrothermal vents; however, anthropogenic sources of mercury are increasing. It was refreshing to find that, in general, and despite both natural and anthropogenic mercury being high in Oregon waters, the levels seen in marine mammals on our coast were still relatively low when compared with levels reported for some of these species in other waters (see Chapter 2). A detailed protocol for total mercury analysis is given in appendix G.

The continued monitoring for mercury in marine mammals is a worthwhile study. These species represent important sentinels of pollution in the marine environment. The availability of tissue for analysis from animals that strand makes the monitoring of mercury a feasible endeavor. Furthermore, the suggestion that mercury from hydrothermal vent activity off the Oregon coast may account for levels of mercury in species such as the Steller sea lion, emphasizes the importance of initiating studies on mercury levels in coastal fish stocks that are primary prey items for marine mammal species.

Appendix C

Box and Whisker Plots

A-Box and whisker plot of THg (mg/kg muscle wet weight).

B-Box and whisker plot of THg (mg/kg muscle dry weight)

C-Box and whisker plot of THg (mg/kg muscle normalized weight)

Appendix D

Log Transformed THg Concentrations

Box and whisker plot showing the distribution of THg from each species. THg was log transformed ($\log(\text{THg ww} + 1) + 1$), to normalize.

Appendix E

Species Linear Regression

Graphs (A-E)- THg ww vs. length(cm), square = male, circle = female, triangle = unknown sex. Linear regression with R-square value in top left hand corner.

A- California sea lion

B- Harbor porpoise

C- Harbor seal

D- Northern elephant seal

E- Steller sea lion

Appendix F

Tukey HSD Analysis of Health Code vs. [THg]

Univariate analysis of variance using total mercury concentration (dw) and health codes 1= health, 2= less health, 3= health issues, 4= sick, 5 unknown. Based on a significance of 0.05.

The Tukey HSD analysis of variance was used. This analysis was performed to answer any questions that could have come up regarding the health of the individual animal and whether its THg concentration could be significantly correlated. This test compared the health code category against the mean THg concentration of all animals with that health code to look for a correlation.

Appendix G

Step-by-Step Mercury Analysis Procedure

A. Archiving tissue sample

1. Muscle tissue should always be collected from the same same area of the animal. I recommend the dorso-lateral region, just posterior to the shoulder blade.
2. Using a stainless steel serrated knife, cut out a piece of muscle approximately 3" cubed. When in doubt, make the piece larger.
3. Double bag tissue and immediately place on ice for transfer to a -20 degree freezer for storage.

B. Mercury analysis

1. Everything needs to be very clean. Anything that touches the tissue must be rinsed with diluted HCl and then further washed with nanopure DI water.
2. Trim the muscle sample to remove all sides that came into contact with air.
3. Cut into fairly small cubes to be blended and homogenized. The homogenization is vital for equal distribution and more accurate results.
4. Blend thoroughly (do not add additional fluids) in a glass walled, stainless steel blade blender.
5. Take two 0.5g samples; one for mercury analysis and the other for desiccation.
6. Record everything that is done, especially the exact weight of the tissue that is taken for analysis and desiccation to three decimal places (for example, 0.498g)
7. Put one of the samples of the slurry (weight known) into a 10ml glass ampule, with 1 ml ultra pure nitric acid and 2 ml nanopure DI water.
8. Flame to seal the tip. Go to Step 11.
9. For desiccation take the other sample of slurry (weight known) and put this into a 2 ml cap-less centrifuge tube and weigh it with the tube (muscle and tube weight). This sample is now ready for desiccation.

10. Put into a vacuum desiccation chamber for a 24 hr. cycle. This is plenty of time to completely dry the tissue. It is imperative to record the dried tissue-tube weight immediately in order to establish the amount of water lost. Water loss is described as a percent of the original tissue weight.

11. Sealed ampules are autoclaved for 60 min @ 100 degrees centigrade. This acts to digest the tissue. Use caution at all times with high heat and corrosive acids.

12. Prepare the Millennium Merlin Mercury Analyzer for operation. All tubing and glassware should be new and free of cracks, splits, or gaps. The carrier gas needs to be either analytical grade argon or helium. I recommend using argon because this will save glassware from contamination. All gas lines must be sealed with Teflon tape and checked for leaks. The software needs to be up to date and operating flawlessly. The newest version of the software can be downloaded from www.psaanalytical.com.

13. Prepare the stock solution, acid converter solution, and calibration standards. All chemicals have to be mercury free analytical grade, which usually means that it needs to be HPLC grade. The stock solution is a 1% HCl mixture of HCl and nanopure DI water. Make lots of this. The acid converter solution is a mixture of concentrated HCl solution and tin (II) chloride or stannous chloride. Calibration standards depend on what you expect to find in terms of concentration. I expected to find between 1-10 ppm, so I made five standards of 0.00, 1.00, 5.00, 10.00, and 20.00 ppm. Use a known mercury standard from NIST such as dogfish muscle. Each of the following mentioned solutions have to be made fresh each day to eliminate contamination.

Acid Converter Solution-	20g SnCl ₂ + 25ml HCl + 1L DI H ₂ O		
Stock Solution-	75ml HCl + 2.5L DI H ₂ O		
Calibration Standards-	0.00 ppm	0.00mg Hg	250ml Stock Soln
	1.00 ppm	0.25mg Hg	250ml Stock Soln
	10.00ppm	2.50mg Hg	250ml Stock Soln

14. After autoclaving samples, break open the top of the ampule and pipet out 1ml of digested tissue and add to 40ml of 1% HCl solution into a 50 ml centrifuge tube. You should now have 41ml of a diluted muscle tissue in a 50ml centrifuge tube.

15. Remember to label everything.

16. The stannous chloride mixture needs to be bubbled with the carrier gas for one hour prior to analysis. This helps eliminate any water and also mixes the solution.

17. We are now ready to set the operating conditions of the software; how long to run a blank through to clean, how long to cycle through each 41ml sample, and how long to clear after the sample cycle. My setup was as follows:

Delay- 20 sec. Analysis- 60 sec. Memory- 80 sec.

Each sample is cycled twice and averaged. This is beneficial but can also be changed if needed. I recommend testing the functions of the machine and trying a few dry runs to figure out what best would fit your needs.

18. Calibration standards must be run each day to establish a background calibration curve. Warming up the machine up before use is critical. The two peristaltic pumps are connected to the appropriate solutions. The first connection is permanently set in the acid converter solution. The second is only put into the 50ml centrifuge tube that is filled with the calibration standard. Each standard is run twice and averaged.

19. With each run, it is important to remember to run duplicates, a method blank, and a known spike. For every ten samples, you will need to run one of each. These samples allow you to calculate your reproducibility, percent error, and your method detection limit. When in doubt run two for every ten.

20. Because the tissues for the mercury analysis were diluted, they need to be reconfigured to their original tissue weight. Calculate what was added to the ampules before the analysis (1ml nitric acid, 2ml H₂O, and 40 ml 1%HCl). For 0.5g tissue this equates to a dilution of 86:1. 43ml of solutions to 0.5g tissue. This value will multiply the mercury concentration that was found after analysis. For example, if the concentration from the mercury analyzer read 0.05 ppm, you would multiply this by 86 to get your actual THg concentration before dilution. $86 \times 0.05 = 4.3$ ppm.
