Abstract

Drought is among the costliest natural hazards developing slowly and affecting large areas, which imposes severe consequences on society and economy. Anthropogenic climate change is expected to exacerbate drought in various regions of the globe, making its associated socioeconomic impacts more severe. Such impacts are of higher concern in Africa, which is mainly characterized by arid climate and lacking infrastructure as well as social development. Furthermore, the continent is expected to experience vast population growth, which will make it more vulnerable to the adverse effects of drought. This study provides the first comprehensive multi-dimensional assessment of drought risk across the African continent as a function of hazard, vulnerability, and exposure. A multi-model and multi-scenario approach is employed to quantify drought hazard using the most recent ensemble of regional climate models and a multi-scalar drought index. Moreover, a rigorous framework is proposed and applied to assess drought vulnerability based on various sectors of economy, energy and infrastructure, health, land use, society, and water resources. Drought risk is then projected for different population scenarios and the changes of drought risk and the role of each component are investigated. In addition, the impacts of climate change on heat-stress mortality risk is assessed across the Middle East and North Africa. The results indicate vast increase for the projected drought risk with varied spatiotemporal patterns. Population growth and climate change will significantly escalate drought risk, especially in distant future. Therefore, climate change mitigation and adaptation planning as well as social development strategies should be carried out immediately in order to reduce the projected adverse risks on human life and society.

Acknowledgements

In the past few years, many people have supported me throughout my PhD, and I am truly indebted to them for their time, help, and concern. First, I would like to acknowledge and thank my advisor, Dr. Hamid Moradkhani, who supervised me in my PhD studies, and I highly benefitted from his knowledge, guidance, and experience. I would like to also thank my dissertation committee members, Dr. Gwynn Johnson, Dr. Max Nielsen-Pincus, and Dr. Paul Loikith for their willingness to serve on my committee and for their valuable comments and feedbacks on my research. Their comments and suggestions helped me significantly improve the quality and clarity of my research.

I should also thank all the post-doctoral associates and graduate students that I had the pleasure to work with in the Water Resources and Remote Sensing Lab, including Arun Rana, Mehmet Demirel, Hongxiang Yan, Sepideh Khajehei, Mahkameh Zarekarizi, and Maysoun Hameed. Our collaborations expanded my knowledge and abilities, and provided me strong leadership and communication skills.

I am also thankful of the kind staff of the Department of Civil and Environmental Engineering, including Megan Falcone and Ariel Lewis, who were always great resources and helped me navigate my work in the department. Moreover, I must express my gratitude to the lovely staff of the International Student Life team at PSU, especially Jill Townley and Yoko Honda, who helped me adapt my life and overcome any cultural shocks.

Finally, I must express my deepest gratitude and appreciation to my family for their continuous and unconditional love, care, and support. Their encouragement motivated me

to strive to achieve my dreams, and I could have not completed this work without their support and patience.

1 Introduction

Climate change and population growth have exacerbated water insecurity in many regions of the globe, and it is expected that they become grand challenges of the society in the twenty first century (Risley et al. 2011; DeChant and Moradkhani 2015; Zhao and Dai 2015). The issue is more concerning in Africa with exceptional population growth and extreme changes in climate which is expected to intensify droughts in many regions of Africa (Dai 2012; Touma et al. 2015). Despite the critical challenges facing the continent, few studies have comprehensively investigated the socioeconomic risks of concurrent changes in climate and population growth in Africa. The current study aims to bridge such scientific gap and assess drought vulnerability and risk in Africa based on a comprehensive multi-dimensional framework to help with future planning and management of resources in order to mitigate drought hazard impacts at regional scales.

1.1 Drought

Drought is a prolonged period of water deficiency (Madadgar and Moradkhani 2013a; Yan et al. 2017). It is among the costliest natural disasters affecting large extents of area and lasting up to several years (Madadgar and Moradkhani 2014a; Ahmadalipour et al. 2017c). Drought can be classified into four different types of meteorological (deficit in precipitation), hydrological (surface and subsurface water deficiency), agricultural (root zone soil moisture deficiency), and socio-economic (failure of water resources systems and market prices) (Mishra and Singh 2010). Drought is a complex phenomenon and among

the most severe natural hazards which is often developed slowly and affecting large areas for a long period of time compared to the eye-catching flash flood events (Van Loon 2015; Ahmadalipour et al. 2017a). It can affect water supply, agriculture, hydropower, river navigation, and it may escalate wildfire risk (Madadgar and Moradkhani 2014a; Turner et al. 2015; Abatzoglou and Williams 2016).

Several drought indices have been developed for quantifying the severity of different types of drought. The Palmer Drought Severity Index (PDSI) is among the first indices proposed for assessing meteorological droughts (Palmer 1965). PDSI considers several water balance variables such as precipitation, soil moisture, and runoff to quantify drought severity (Liu et al. 2016; Yan et al. 2016). Decades later, the Standardized Precipitation Index (SPI) was developed as a simple meteorological drought index focusing solely on precipitation variation (Mckee et al. 1993). SPI then became one of the most popular drought indices and researchers investigated its applicability for other types of drought (Bloomfield and Marchant 2013; Musuuza et al. 2016). Similar drought indices were developed using the same formulation while considering different variables such as runoff or streamflow (Shukla and Wood 2008; Vicente-Serrano et al. 2012b). Later on, the Standardized Precipitation Evapotranspiration Index (SPEI) was introduced by Vicente-Serrano et al. (2010) as a multi-scalar index based on a climatic water balance between precipitation and potential evapotranspiration, which allows for considering the effects of temperature on drought.

Despite the extreme social, economic, and ecological impacts, drought is not yet thoroughly understood mainly due to the complexity and variety of drought origins, uncertain mechanisms for drought advancement and recovery, and the multiscale spatiotemporal characteristics of it (Sohrabi et al. 2004; Hobbins et al. 2016; Wang et al. 2016; Ahmadalipour and Moradkhani 2017).

Recent studies have discussed that the agricultural failing and water shortages, both caused or affected by drought, have exacerbated the social structure and spurred the ongoing violence that began in Syria in March 2011 (Gleick 2014; Kelley et al. 2015). Researchers have reported that drought and war will soon increase the possibility of extensive famine in four countries (i.e. Somalia, South Sudan, Nigeria, and Yemen) endangering more than 20 million lives (Gettleman 2017).

Drought is particularly more critical in Africa as it imposes the most negative consequences and causes famine and land degradation (Scrimshaw 1987; Lyon 2014). There were a total of 382 reported drought events in Africa between 1960-2006 which affected 326 million people (Gautam 2006; Shiferaw et al. 2014). Prolonged droughts impose the most considerable climatic impact on gross domestic product (GDP) per capita growth in Africa (Brown et al. 2011). The Ethiopia/Sudan drought of 1974 and the Sahel drought of 2007 were the worst natural disasters of the world in the past decades causing 450,000 and 325,000 deaths, respectively (Vicente-Serrano et al. 2012a). The 2010-2011 drought in the Greater Horn of Africa was the worst drought in the past 60 years in the region and affected over 12 million people (Zaitchik et al. 2012; Checchi and Robinson

2013; Dutra et al. 2013), causing massive migration, extreme famine, and death of over 260,000 people (Loewenberg 2011; Nicholson 2014).

1.2 Climate Change

Multitude of studies have demonstrated that the global climate has changed in the past decades primarily due to the increase in concentration of greenhouse gases (IPCC 2014; Rana and Moradkhani 2016). Numerous studies have pointed out the impacts of climate change on precipitation and temperature (Halmstad et al. 2013; Rana and Moradkhani 2016; Rana et al. 2016), extreme events (Halmstad et al. 2013; Najafi and Moradkhani 2014; Zarekarizi et al. 2016), drought (Madadgar and Moradkhani 2013b; Ahmadalipour et al. 2016), and flood (Moradkhani et al. 2010; Jung et al. 2011; Najafi and Moradkhani 2015a). It has been concluded that climate change will exacerbate the impacts of hydrologic and weather extremes in many parts of the globe (Jung et al. 2012). Such impacts are not uniform in different regions and it has been shown that the majority of Africa will be vigorously affected by climate change (Sheffield and Wood 2008; Asadi Zarch et al. 2014; Zhao and Dai 2016; Carrão et al. 2017).

The hydrological impacts of climate change on different geographical domains, along with information regarding climate modeling are elaborated in more details in Chapter 2.

1.3 Vulnerability, Hazard, and Risk

Vulnerability is defined as the level of susceptibility of a system to harm from exposure to stresses and hazards (Adger 2006). It identifies the degree that a system is unable to adapt to the adverse impacts of a shock. Vulnerability is often characterized by components of exposure and sensitivity to external stresses (Parry et al. 2007). Therefore, the same natural disaster poses different consequences in various regions due to their distinct vulnerabilities (Vicente-Serrano et al. 2012a).

The concept of vulnerability has been used in different subjects including economics, sociology, urban studies, environment, and natural hazards. Although there is a semantic debate on the terminology among different contexts, the concept of vulnerability used in the United Nations and the Intergovernmental Panel on Climate Change (IPCC) attributes the components of risk through exposure and sensitivity (Adger 2006; Füssel 2007; O'BRIEN et al. 2007; IPCC 2014).

Comprehending drought vulnerability improves preparedness of a region and limits the devastating impacts of drought hazard at national and regional levels (Naumann et al. 2014). However, quantifying vulnerability is a great challenge as it depends on biophysical and socioeconomic sectors, and requires expert knowledge (Adger 2006; Shiferaw et al. 2014). Assessing drought vulnerability is particularly more complex because of the diversity of the natural and social systems impacted by drought. Furthermore, there is no common approach for quantitative assessment of drought vulnerability (Vicente-Serrano et al. 2012a). Thus, it is crucial to investigate different components that will be affected by

drought including social, economic, health, and environmental, for vulnerability assessments (Smit et al. 1999).

Studies have discussed that the vulnerability of communities and ecosystems to drought has increased in Africa over the past decades mainly due to population growth and over-exploitation of natural resources (Antwi-Agyei et al. 2012). Therefore, there is a need to assess drought vulnerability in a quantitative and objective manner to understand the vulnerability and its historical variations, especially over Africa.

A few studies have assessed drought vulnerability in Africa. Eriksen et al. (2005) assessed drought vulnerability of Kenya and Tanzania based on few socio-economic factors and food insecurity. Eriksen and O'Brien (2007) investigated how climate change adaptation can reduce poverty and vulnerability in Kenya. Schilling et al. (2012) investigated the impacts of climate change on drought hazard in the Sahel region. They quantified drought vulnerability according to agricultural and economic sectors. Antwi-Agyei et al. (2012) carried out a regional drought vulnerability analysis based on the impacts of drought on crop yield in Ghana. Shiferaw et al. (2014) investigated drought vulnerability and impacts in Africa based on agricultural yield and economic losses for the period of 2006-2012. More recently, Naumann et al. (2014) presented a comprehensive assessment of drought vulnerability at national level in Africa. They studied 17 indicators for quantifying drought vulnerability from four components of renewable natural capital, economic capacity, human and civic resources, and infrastructure and technology.

Drought hazard is commonly quantified by a set of drought indicators (Blauhut et al. 2015a). Standardized drought indices are among the most common tools employed for

investigating drought hazard. The drought indices are reviewed in multitude of studies to point out their differences and applications (Mishra and Singh 2010; Dai 2011; Schyns et al. 2015).

Drought risk is characterized as a function of hazard, vulnerability, and exposure (Blauhut et al. 2015b; Gudmundsson and Seneviratne 2016). Therefore, aggravation of drought hazard (e.g. exacerbation of drought severity) eventuates in drought risk escalation, if other variables are kept constant. Meanwhile, it also implies that despite a magnifying hazard, drought risk can be mitigated by reducing vulnerability. The dynamic nature of both vulnerability and hazard leads to dynamic and time-varying nature of drought risk, which should be considered in risk assessments (Birkmann et al. 2013).

While many studies have used the term “risk” in their drought assessment, most of them have actually investigated drought hazard, as the components of vulnerability or exposure were ignored (Kam et al. 2014; Cook et al. 2015). Meanwhile, few studies have practically investigated drought risk and vulnerability using socio-economic factors (Antwi-Agyei et al. 2012; Schilling et al. 2012; Blauhut et al. 2015b; Naumann et al. 2015). The majority of studies focus solely on hazards, due to the difficulties in characterizing social indicators of vulnerability (Naumann et al. 2014).

In general, the frameworks for understanding vulnerability and risk can be classified into four different approaches, each having a distinct viewpoint. The four vulnerability assessment approaches are distinguished based on their root in (1) political economy; (2) social-ecology; (3) climate change system science; and (4) a holistic view (Birkmann et al. 2013).

1.4 Objectives of Dissertation

The objective of this dissertation is to assess and project drought risk in Africa, as a function of vulnerability, hazard, and exposure. Therefore, the three main components should be studied separately. The primary objectives of the study can be categorized as follows:

- i. Performing a comprehensive assessment of hydrologic and socio-economic variables to analyze drought vulnerability in Africa (Chapter 3)
- ii. Investigating decadal changes of drought vulnerability for each country during the past decades, and addressing the countries that indicate low progress and identifying sectors that require more attention (Section 3.4.1)
- iii. Analyzing the historical variations and trends of drought vulnerability for each country and projecting it for future period (Section 3.4.2)
- iv. Utilizing climate data and multi-scalar drought indices to investigate historical and future changes of drought hazard over Africa (Section 4.4.1)
- v. Assessing the population changes of each African country in the historical period and future projections (Section 4.4.2)
- vi. Utilizing vulnerability, hazard, and exposure at national-scale to assess drought risk of each country (Section 4.4.3)
- vii. Providing decadal risk maps for different future scenarios, and investigating the role of each component of risk (Section 4.4.3)

- viii. Apart from the drought risk, the impacts of climate change on heat-related mortality risk will also be assessed, and its spatiotemporal patterns will be characterized (Chapter 5).

2 Climate Change Impact Assessment

2.1 Background

It is generally accepted that global climate has changed and it is affecting environmental systems at both global and regional scales (Ahmadalipour et al. 2017b). Climate change is expected to have severe effects on global hydrological cycle along with several natural and social parameters such as water availability, crop yield, health, and ecology (Mote and Salathé 2010; Fan et al. 2014). Global climate models (GCMs) are large-scale coarse-resolution models developed based on atmospheric, oceanic, and chemical processes in the Earth system. GCMs provide simulations of climate variables during the historical period as well as future projections for different scenarios. The most recent ensemble of climate models were provided by the Coupled Model Intercomparison Project Phase 5 (CMIP5) (Taylor et al. 2012). The future projections of CMIP5 GCMs are generated for four different scenarios (i.e. representative concentration pathway; RCP) depending on the concentration of greenhouse gases.

This chapter provides a brief overview of the climate modeling and climate change impact analyses I performed across various geospatial domains.

2.2 Global Climate Models (GCMs)

Global climate models (GCMs) are the primary tools utilized for assessing the impacts of climate change. Different institutions have developed GCMs with various

assumptions and diverse initial conditions at distinct spatial resolutions. Uncertainty is an inevitable characteristic for future climate projections (Najafi et al. 2011; Ahmadalipour et al. 2015; Hawkins et al. 2015). Furthermore, the varying nature of climate and the unknown concentration of greenhouse gases aggravate the uncertainty at annual to decadal timescales, respectively (Mote and Salathé 2010; Ahmadalipour et al. 2017b). Bayesian frameworks have been developed and utilized in various model averaging assessments to reduce the uncertainty of climate model simulations and provide a likely prediction scenario (Madadgar and Moradkhani 2014b; Sun et al. 2014a, 2016; Najafi and Moradkhani 2015b).

Regional climate models (RCMs) are the models developed using GCMs for the lateral boundary conditions of a specific region. Several studies have evaluated the performance of GCMs and RCMs for various regions of the globe, and it has been shown that RCMs are generally more accurate and less biased than their driving GCMs (Saini et al. 2015; Diasso and Abiodun 2017; Ring et al. 2017). Advanced bias-correction methods have been proposed in recent years to generate more reliable simulations at short- and long-range predictions (DeChant and Moradkhani 2014; Madadgar et al. 2014; Khajehei and Moradkhani 2017; Khajehei et al. 2017).

Figure 2-1 shows the global mean air temperature increase calculated at decadal timescale for 9 CMIP5 GCMs and their ensemble mean for two representative concentration pathways of RCP4.5 (moderate increase in greenhouse gases) and RCP8.5 (business as usual scenario). RCP4.5 leads to about 2°C global temperature rise compared to the pre-industrial era, whereas the same for RCP8.5 is above 5°C. The difference

between the two scenarios is merely noticeable in near future, whereas they indicate vast differences after 2060s.

Figure 2-1. Global decadal mean air temperature increase calculated from 9 GCMs and the ensemble mean for RCP4.5 (top) and RCP8.5 (bottom).

2.3 Regional Impacts of Climate Change

Contiguous US: The regional impacts of climate change are not necessarily the same as the global impacts. Furthermore, the seasonal patterns are not necessarily similar either. For instance, Ahmadalipour et al. (2016) assessed the impacts of climate change across the contiguous U.S. (CONUS). They used 21 downscaled CMIP5 GCMs provided by NASA (NEX-GDDP) at 0.25 degree spatial resolution for the period of 1951-2099 using two future scenarios of RCP4.5 and RCP8.5. **Figure 2-2** presents the seasonal changes of

precipitation in 50-year future periods compared to the historical period of 1951-2000. The figure shows the differences in seasonal and regional changing patterns of precipitation. Similarly, **Figure 2-3** shows the seasonal changes of mean air temperature over the CONUS.

Figure 2-2. Future changes of seasonal precipitation compared to the historical period of 1951-2000 across the CONUS calculated from 21 downscaled CMIP5 GCMs.

Figure 2-3. Same as Figure 2-2, but for mean air temperature.

Pacific Northwest US (PNW): The uncertainties in GCM parameterization and the existence of large biases in raw GCM outputs given the model development assumptions have resulted in overestimation of precipitation (Rupp et al. 2013; Ahmadalipour et al. 2015). Ahmadalipour et al. (2017b) utilized 10 downscaled CMIP5 GCMs at 1/16° spatial resolution to understand the impacts of climate change on seasonal climate variables across sub-basins of Columbia River Basin. Bayesian Model Averaging was implemented to generate likely future climate projections. Employing data from 10 climate models, two future scenarios (RCP4.5 and RCP8.5), and two downscaling techniques, the model, scenario, and downscaling uncertainty were characterized for various variables, respectively. **Figure 2-4** shows the annual precipitation projections for 10 sub-basins of

Columbia River Basin. Similarly, the annual projections of maximum near surface air temperature (TMax) are presented in **Figure 2-5**.

Figure 2-4. Projection of annual precipitation for each sub-basin using BCSD dataset. The figure is generated using spatially averaged annual precipitation over each sub-basin for GCMs and BMA.

Figure 2-5. Similar to Figure 2-4, but for maximum near-surface air temperature (TMax).

The spatial changes of climate variables across the Columbia River Basin are shown in **Figure 2-6** (Ahmadalipour et al. 2017b).

Figure 2-6. Long-term seasonal changes of precipitation (top) and temperature (bottom) for summer (JJA) and winter (DJF) from BMA projections.

The ensemble of climate projections were then utilized to characterize the uncertainties of climate projections from various sources, and the results are shown in **Figure 2-7**. The results indicated that model uncertainty is the primary source of uncertainty in climate projections across the PNW. However, downscaling uncertainty demonstrates to be a considerable source of uncertainty, especially in summer (Ahmadalipour et al. 2017b).

Figure 2-7. Fraction of the total variance of future projections of precipitation (top) and temperature (bottom) for each season.

Middle East and North Africa (MENA): The changes of annual maximum air temperature across the Middle East and North Africa (MENA) are calculated from 17 RCMs at 0.44 degree spatial resolution for near future (2010-2039), intermediate future (2040-2069), and distant future (2070-2099) compared to the historical period simulations. Results are shown in **Figure 2-8**. The figure indicates that although the global mean temperature change (as shown in **Figure 2-1**) is about 2°C in intermediate future, the maximum air temperature is expected to increase over 4°C in many regions.

Figure 2-8. Changes of annual maximum air temperature across the Middle East and North Africa (MENA) calculated from 17 CORDEX RCMs.

To better emphasize the regional impacts of climate change, the changes of maximum air temperature (ΔT_x) are plotted against the global mean air temperature changes (ΔT_{global}) for various regions across the MENA, and the results are presented in **Figure 2-9**. The figure shows that the regional changes of maximum air temperature is expected to be much higher than the global warming rate, especially for Mediterranean regions.

Figure 2-9. Regional changes of maximum air temperature (ΔT_x) compared to the global warming rate (ΔT_{global}).

2.4 Climate Change and Drought

Numerous studies have investigated the impacts of climate change and anthropogenic warming on hydrological patterns and drought (Swain and Hayhoe 2014; Ahmadalipour et al. 2016). The rise in global temperature will influence various hydrological processes such as evapotranspiration and snowmelt (Diffenbaugh et al. 2013; Sima et al. 2013). It has been shown that climate change will affect the hydrologic cycle and its seasonal patterns, which will consequently alter drought characteristics (Dai 2012; Diffenbaugh et al. 2015; Duffy et al. 2015). For instance, several studies investigated the 2011-2014 California drought to diagnose the attribution of anthropogenic warming on it

(Shukla et al. 2015; Williams et al. 2015; Mao et al. 2015), and concluded that climate change exacerbated the severity of California drought (Diffenbaugh et al. 2015; Williams et al. 2015).

Ahmadalipour et al. (2016) employed 21 downscaled CMIP5 GCMs and assessed the impacts of climate change on seasonal drought characteristics across the CONUS. They utilized the SPEI and SPI, and studied the changes of drought extent, intensity, and frequency. **Figure 2-10** and **Figure 2-11** show the changes of drought extent according to the SPEI and SPI, respectively. Both of the indices were calculated at 3-months accumulation period to better capture the seasonal patterns of drought. The figures indicate increasing drought extent for most regions during summer, and illustrate the role of temperature on drought exacerbation, where the SPEI drought extent is much higher than that of SPI, especially in summers. Moreover, linear trend of drought indices are calculated for the 21 GCMs during the future period of 2005-2099, and the ensemble mean trend of the SPEI and SPI are plotted in **Figure 2-12** and **Figure 2-13**, respectively. It should be noted that a trend of -0.02 in SPEI means that in 25 years, the mean value of SPEI will decrease by 0.5 (-0.02×25), which is significant given that the SPEI thresholds of -1 , -1.5 , and -2 represent moderate, severe, and extreme drought conditions, respectively.

Figure 2-10. Spatial extent of drought according to SPEI-3 for the historical of 1950-2005 and two future scenarios during 2006-2099.

Figure 2-11. Same as Figure 2-10, but calculated for SPI-3.

Figure 2-12. Long-term trend of drought indices for the future period of 2005-2099 according to the SPEI-3.

Figure 2-13. Same as Figure 2-12, but for the SPI-3.

Faramarzi et al. (2013) employed SWAT hydrologic model and used five CMIP3 Global Climate Models (GCMs) with four future scenarios to investigate the impacts of climate change on water availability in Africa. They found that in general, the mean

quantity of water would slightly increase in Africa as a whole, while diverse spatial patterns exist. Overall, the changes in seasonal patterns of precipitation and the population growth are expected to exacerbate drought risk and per capita water availability in Africa (Shiferaw et al. 2014).

3 Drought Vulnerability in Africa

3.1 Background

Regional drought vulnerability assessments are of high importance for local water resource management and drought preparedness. Studies have investigated drought vulnerability in Bangladesh (Shahid and Behrawan 2008), China (Simelton et al. 2009), Morocco (Schilling et al. 2012), South Korea (Kim et al. 2015), and India (Singh and Kumar 2015) for such purposes. However, the regional assessments are unable to reliably address the resilience and adaptive capacity from a comparative viewpoint. On the other hand, some other studies have assessed vulnerability at global scale (Fraser et al. 2013; Carrao et al. 2016). However, comparing developed countries having abundant water resources (e.g. Sweden) and poorly developed countries with low access to freshwater (e.g. Chad) does not accurately capture the regional characteristics of vulnerability. In other words, country-level vulnerability assessments should be implemented for the countries with an overall climatological or geopolitical similarity.

One of the primary shortcomings of most drought vulnerability assessments is their static formulation and investigation, which does not allow for diagnosing the effectiveness of adaptation plans nor capable of comprehending the influence of different factors through time. Furthermore, many studies solely focused on economical or agricultural factors of vulnerability and ignored other aspects such as health and social development. Considering the devastating impacts of drought in the least developed countries of Africa, it is crucial to account for as many factors as possible.

The present study provides a comprehensive assessment of drought vulnerability across the African continent based on a multi-dimensional analysis of several different socio-economic components. Drought Vulnerability Index (DVI) is quantified and analyzed for each country during the historical period. It is then projected for future period in order to provide a probable DVI for each country based on its long-term historical variations and trends. The study builds up on the previous drought vulnerability assessments through the following research tasks:

- Identifying the dominant independent factors of drought vulnerability in Africa
- Providing a reliable weighting method for probabilistic calculation of DVI from different factors
- Assessing the historical changes of DVI for each country in Africa during 1960-2015 and projecting DVI for 2020-2100
- Detecting the most and least vulnerable countries in Africa, and analyzing their changes over time

3.2 Data

The first step for quantifying drought vulnerability is to identify the relevant factors that address different dimensions of drought impacts including environment, health, society, and economy. Since the impacts of drought on natural and human resources are distinct for different regions, it is not possible to define a single measurement of drought vulnerability suitable for all regions. Therefore, selecting relevant factors requires expert knowledge about the study region.

Here, vulnerability factors are divided into six main categories (components) including economy, energy and infrastructure, health, land use, social, and water resources. Different data sources such as Food and Agricultural Organization (FAO) of the United Nations and the World Bank are explored to investigate data for each component.

A total of 61 factors were initially investigated mainly from two data sources; the AQUASTAT as FAO's global water information system and the World Bank. Some of these factors were eliminated due to their discontinued or limited availability. After preliminary investigations and rational reasoning, 36 factors were remained. Each factor should at least meet the following requirements in order to be considered for further analysis:

- a. The factor should be continuously available for at least a decade in the historical period.
- b. The factor should provide data for at least half of the African countries.

Analyzing the factors for the above requirements eliminated 6 more of them, and 30 factors were remained. Then, the factors were normalized and a multi-collinearity analysis was performed to assess the independence of each pair of factors, which eliminated two more factors. The test is described in details in the Methodology section.

Eventually, an ensemble of 28 factors were selected as the indicators of drought vulnerability. The 28 factors and their corresponding components are presented in **Figure 3-1**. The correlation of each factor to the overall vulnerability is indicated in the brackets. The figure also shows the number of countries that have data for each factor in each year.

Figure 3-1. The 6 components and 28 factors considered in the analysis, and the availability of each factor during the historical period. The signs in the brackets indicate the correlation of the factor to the overall vulnerability. In each particular year, a factor is eliminated if it does not provide data for at least half of the countries.

The data for each factor is averaged in 5-year periods for each country during 1960-2015 since many of the factors have missing data in some years and averaging will eliminate the issue of missing data. It will also improve the overall accuracy of the calculated vulnerability index. Moreover, the assessment is not applied to the extremely small countries and islands, as the traditional definition of drought and its impacts are not practically applicable in such places. Finally, for the case of the countries that were

established in recent decades (e.g. South Sudan gained independence from Sudan in 2011), both countries were considered and assessed as a whole to utilize long-term data.

It should be noted that population is not considered as a separate factor. In fact, population is incorporated in 20 of the chosen factors, and 6 other factors are independent of population (i.e. percentage of agricultural land, percentage of forest land, inflation rate, life expectancy at birth, agricultural machinery, and the human development index). Only two of the chosen factors were originally dependent of population (i.e. total reserves and net migration), both of which were divided by the corresponding population of the countries in each year, acquired from the population estimates of the United Nation (2015). Therefore, instead of using population as a single factor, it is implicitly considered in the majority of the chosen factors.

3.3 Methodology

The drought vulnerability assessment of this study is performed in seven steps as follows:

1. Data selection, download, and reformatting
2. Normalizing factors and calculating vulnerability for each factor
3. Multi-collinearity test and eliminating redundant factors
4. Weighting and averaging to compute Drought Vulnerability Index (DVI)
5. Cluster analysis and categorizing countries based on their vulnerability to drought
6. Change-point analysis to diagnose for any substantial changes in historical DVI

7. Future DVI projection

The flowchart for calculating drought vulnerability and the main analyses applied in this study are presented in **Figure 3-2**. Each step of the assessment is described in more details in the following.

Figure 3-2. The methodology employed to assess data, calculate Drought Vulnerability Index (DVI), and project it for the future period.

3.3.1 Normalizing Factors

Each of the 28 chosen factors (shown in **Figure 3-1**) are normalized among all countries and through time to enable comparing different variables and to comprehend the temporal changes. This is carried out considering the minimum and maximum value of each factor during the historical period for all countries according to Equation 3-1 as follows:

$$\left\{ \begin{array}{ll} Z_{i,t} = \frac{X_{i,t} - X_{min}}{X_{max} - X_{min}} & \text{For the factors with a positive correlation to the overall vulnerability} \\ Z_{i,t} = 1 - \frac{X_{i,t} - X_{min}}{X_{max} - X_{min}} & \text{For the factors with a negative correlation to the overall vulnerability} \end{array} \right. \quad \mathbf{3-1}$$

where $X_{i,t}$ is the value of a particular factor for the i^{th} country and time t , and X_{min} and X_{max} represent the minimum and maximum values of the factor among all countries throughout the time, respectively. In both cases, $Z=0$ and $Z=1$ indicate the lowest and highest vulnerability, respectively.

It should be noted that in each case, the outliers are identified if they are larger than the upper limit ($UL = q_3 + 1.5 \times IQR$) or less than the lower limit ($LL = q_1 - 1.5 \times IQR$), where q_1 and q_3 are the first and third quartiles of data indicating 25th and 75th percentiles, respectively, and IQR is the interquartile range ($IQR = q_3 - q_1$). Therefore, $Z > UL$ and $Z < LL$ are eliminated in each factor for accurate normalization of the factors. For instance, considering the GDP per capita, a high GDP associates with lower vulnerability. Therefore, it has a negative correlation with the overall vulnerability and the bottom equation should be used for normalization. Some of the countries indicate much higher GDPs than other

African countries. For instance, Egypt is a positive outlier of GDP per capita in almost all years (thus, indicating the lowest vulnerability, i.e. $Z=0$). Hence, the outlier values of GDP were identified and removed, and $Z=0$ was assigned to the GDP per capita of Egypt in the corresponding years. Similar procedure is applied to each of the 28 factors separately.

3.3.2 Multi-collinearity (Independence) Test

After normalizing the data, all the normalized factors range between 0 and 1. Some of the factors may be correlated and may introduce redundancy. Therefore, the factors should be examined for dependency. In order to investigate the existence of a multi-collinearity due to dependent factors, the Variance Inflation Factors (VIF) method is applied on each pair of the normalized factors (O'brien 2007; Kim et al. 2015). The VIF is a simple measure for the degree of multi-collinearity among variables:

$$VIF = \frac{1}{1 - R^2} \quad 3-2$$

where, R is the spatial correlation of a pair of factors. A value of $VIF > 4$ denotes that the variables are statistically insignificant due to multi-collinearity and it implies a dependence between the considered variables. In other words, if two normalized factors show very similar spatial pattern, they are highly correlated and one of them should be eliminated.

In this study, the VIF test is applied to each pair of normalized factors during 1990 to 2015, as these years provide data for most countries and most factors. The results of the VIF test indicate that the gender-specified factors that were initially considered (i.e. life

expectancy at birth for male/female and unemployment rate for male/female) are highly correlated between the genders and indicate $VIF > 4$ for all the chosen years. Therefore, for both cases, the data is averaged between the genders and the gender-neutralized factors are utilized for quantifying drought vulnerability. The rest of the factors did not indicate any dependence and resulted in $VIF < 2$. Therefore, the results of the VIF test lead to selection of a total of 28 independent factors for quantifying drought vulnerability.

3.3.3 Weighting and Averaging

Drought Vulnerability Index (DVI) in each year is calculated by weighted averaging of the ensemble of 28 normalized vulnerability factors. In other words, DVI can be viewed as a multi-dimensional metric that can be decomposed to measure the effect of an individual factor and analyze the adaptation plans of a country.

Three different weighting methods are implemented in this study to calculate DVI:

- a. Simple averaging (equal weights)
- b. Random weighted averaging
- c. Component averaging

The first method (i.e. simple averaging) treats all factors with equal importance and assigns a weight of $\frac{1}{n}$ to each of the factors, where n is the total number of available factors in a particular year for a specific country (shown in **Figure 3-1**).

The assigned weights may affect the final value of DVI. Therefore, random weighted averaging is proposed and applied in order to provide a probabilistic measure of DVI and to investigate and minimize the sensitivity of the calculated DVI to the chosen weighting method. An ensemble of 1000 set of uniform random weights were generated for each year and each country, and they were applied to the factors in order to obtain 1000 set of DVI values for each country in each year. The distribution of the 1000 DVIs will reveal the effect of the assigned weights on the calculated vulnerability.

Lastly, the component averaging method is utilized to calculate the DVI for each component by applying equal weights to the factors of each component in each year. Component averaging will be beneficial for understanding the historical changes of vulnerability and determines the resilience of each country in each component, and will also provide valuable information for establishing long-term adaptation plans for improving drought vulnerability of African countries.

3.3.4 Cluster Analysis

Cluster analysis is a common method for classifying data into sub-groups (clusters) based on their similarities (Wilks 2011; Ahmadi et al. 2015). The dendrogram plots of the cluster analysis provide apprehensible graphical illustration of the (dis)similarities among various observations. In this study, we have employed the linkage function in order to create an agglomerative hierarchical cluster tree (a bottom up approach where each observation starts in its own cluster and pairs of clusters are merged) from the DVI of all countries using the unweighted average distance algorithm (known as group average). The

linkage function is calculated based on the average distance between all pairs of objects in any two clusters. Then, the pairwise Euclidean distance between DVIs is used to obtain the optimal leaf ordering for the hierarchical clustering, and the results are plotted here using a polar dendrogram. For more information about the details of cluster analysis and its different options, readers are referred to Wilks (2011).

3.3.5 Change-Point Analysis

DVI is calculated for the historical period of 1960-2015 for each country as described. The factors used for calculating DVI varies through time, and this may result in sudden changes in the time-series of DVI. Since the historical variations of DVI in each country is supposed to be utilized for projecting future DVI, it is necessary to determine if any substantial change has happened in the time-series of DVI for each country. The change-point analysis is a useful tool for diagnosing whether a change has taken place according to confidence intervals (Taylor 2000).

The procedure for conducting a change-point analysis is based on a combination of cumulative sum charts (CUSUM) for the original time-series as well as the bootstrapped data from a large ensemble of randomly resampled time-series of the original data. Let $D_1, D_2, \dots, D_{12}$ represent the DVI time-series for a particular country in 1960, 1965, ..., 2015, respectively. The average DVI is calculated as:

$$\bar{D} = \frac{D_1 + D_2 + \dots + D_{12}}{12} \quad \text{3-3}$$

Then, the initial cumulative sum is assigned zero ($S_0 = 0$), and the subsequent cumulative sums are calculated as follows:

$$S_i = S_{i-1} + (D_i - \bar{D}) \quad \mathbf{3-4}$$

S_i is the cumulative sum and always ends at zero (in this case, $S_{12} = 0$). An upward slope in the CUSUM chart indicates a period that the values are higher than the overall average, and vice versa. Therefore, a sudden change in the direction (slope) of the CUSUM implies a sudden change in the data. An estimator of the magnitude of change is the range of CUSUM (S_{diff}), which is a practical choice regardless of the distribution and even if multiple changes have occurred. It is defined as:

$$S_{diff} = S_{max} - S_{min} \quad \mathbf{3-5}$$

where S_{max} and S_{min} represent the maximum and minimum values of S_i , respectively.

In order to determine if a change has occurred at a certain confidence level, a bootstrap analysis is performed. For such purpose, a large ensemble of randomly reordered samples of data with the same length and without replacement is generated ($D_1^0, D_2^0, \dots, D_{12}^0$). Then, the bootstrapped CUSUM is calculated ($S_0^0, S_1^0, \dots, S_{12}^0$), and the magnitude of change (S_{diff}^0) will be determined. The procedure is applied to each of the resampled time-series. A confidence level is then calculated as:

$$Confidence\ Level = \frac{n}{N} \times 100\% \quad \mathbf{3-6}$$

Here n is the number of bootstraps where $S_{diff}^0 < S_{diff}$, and N is the total number of bootstraps. In this study, $N=10,000$ bootstraps are generated to reliably investigate the change-point in each country. The 95% confidence level has been proposed as a minimum threshold for concluding that a significant change has occurred (Taylor 2000). After detecting the existence of a change, the farthest point of the CUSUM from zero ($\max|S_i|$) indicates the last point before the change happened.

3.3.6 Future Drought Vulnerability Projection

After applying the change-point analysis and determining whether a change has occurred or not, the change in the trend of DVI is also considered and the longest reliable continuous historical period of DVI is determined for each country. Then, a regression model is fitted to the time-series of DVI for each country and it is extrapolated into the future period of 2020-2100. Different regression models are evaluated including exponential, logarithmic, linear, polynomial, and power, and the appropriate function is chosen based on the highest coefficient of determination (R^2), the lowest root mean square error (RMSE), and considering the theoretical thresholds of DVI (which should be between 0 to 1, according to the definition). Therefore, although polynomial functions might yield to high R^2 in some cases, they did not satisfy the threshold requirement in most cases. The results of DVI projection and the regression functions used for each country are discussed in more details in the results section.

3.4 Results and Discussion

The results of vulnerability assessment are divided into three sections. At first, the characteristics of DVI are investigated during the historical period. Then, the future projections of DVI are presented and discussed. Finally, the calculated drought vulnerability indices are evaluated according to the historical observed droughts and their impacts.

3.4.1 Historical Assessment of DVI

The 28 independent normalized factors are averaged for each country in each 5-year period to calculate DVI using the simple averaging method. **Figure 3-3** shows the DVI of each country calculated using the simple averaging (arithmetic mean) of the corresponding factors in each year. From the figure, the overall drought vulnerability has decreased in some regions over the past decades. This is especially perceived for the western Saharan countries (i.e. Mali, Niger, and Chad) where DVI values range up to 0.8 in the 1970s and 1980s, and decrease to about 0.6 in recent years. In general, the northern countries of the African continent (i.e. Egypt, Libya, Tunisia, and Algeria) indicate the lowest DVI in most years, followed by South Africa and Morocco. It is worth mentioning that all of these countries receive low annual precipitation (less than 400mm per year). However, their economy and infrastructure are more developed than the majority of African countries. Furthermore, the total water resources of a country is not solely dependent on its rainfall. In fact, many countries depend on transboundary sources for a large portion of their water resources. For instance, Egypt receives about 97% of its total

water resources from the Nile River which originates in other countries (FAO 2016). Therefore, albeit receiving limited precipitation, Egypt is among the least vulnerable countries in Africa based on the water resources components.

Figure 3-3. Spatial changes of Drought Vulnerability Index (DVI) calculated using simple averaging (arithmetic mean) of the corresponding factors in each year during the historical period.

The time-series of DVI for the period of 1960-2015 is utilized to apply cluster analysis. **Figure 3-4** shows the polar dendrogram of the cluster analysis results. The linkage function determines the similarities among countries (the connections and the linkage

distance) and the optimal leaf order indicates the order of countries (from top to bottom). In general, the connected countries are more similar to each other, and it continues with the hierarchy of the dendrogram. For instance, Egypt and Algeria are very similar (in terms of vulnerability) since they are connected. Then, these two countries are similar to Tunisia, connected at the next level. Furthermore, the order of countries in the dendrogram indicate their overall DVI value. In other words, the first countries of the plot (Equatorial Guinea, Gabon, and so on) generally have lower DVI than the last countries of plot (Mali, Rwanda, and so on). A dendrogram may be crossed (cut) at any linkage distance and the generated branches will indicate an individual cluster of similar countries. In this case, considering *Linkage Distance* = 0.65, three separate clusters are created representing low, medium, and high drought vulnerability, which are plotted in green, yellow, and red, respectively. The number of clusters will change according to the chosen linkage distance, whereas the order of countries and their connections are fixed.

Figure 3-4. Polar dendrogram representing the results of clustering DVI using the hierarchical cluster analysis based on the average Euclidean linkage distance and optimal leaf ordering. In general, the green, yellow, and red colors indicate countries with low, medium, and high drought vulnerability, respectively.

Figure 3-5 represents the DVI of each country calculated using the random weighted averaging. Considering a particular country and a particular year, the boxplots show the distribution of the 1000 DVIs for each year. In general, the number of factors for quantifying DVI is higher in recent years than the earlier decades, and the range of DVI (boxplot quartiles) is generally smaller as well. This implies that the calculated DVI is less

sensitive to the chosen weights in recent years. **Figure 3-5** also identifies the temporal variations of DVI during the past decades. Some of the countries show minor variations of DVI in the historical period (e.g. Kenya). In some cases, there is an obvious abrupt change in DVI. For instance, Algeria indicates DVI values of higher than 0.4 with a decreasing trend until 1985, whereas DVI values of about 0.25 are found after 1990 with a slightly increasing trend. The contrast is found for Mali, where slightly increasing DVI values of above 0.8 are followed by decreasing DVIs ranging about 0.6, prior and after 1990, respectively. These changes are identified and discussed in more details for future DVI projections.

Figure 3-5. Drought Vulnerability Index (DVI) of each country calculated using the random-weighted averaging method.

The median of boxplots of **Figure 3-5** can be used as a likely prediction of DVI in each year. In order to understand the differences between the DVI calculated from simple averaging method and the DVI from the random weighted averaging, the results for 1995 and 2015 are plotted against each other in **Figure 3-6**. Both these years have the highest

number of available factors and thus, the DVIs have high reliability. In the figure, the countries are ordered according to their DVI value acquired from the simple averaging method. Therefore, the figure also indicates the changes of countries' drought vulnerability in 20 years. In **Figure 3-6**, the set of 1000 DVIs from random weighted averaging method are plotted using boxplots and the simple averaged DVIs are shown in green asterisks. In general, the DVI from simple averaging method is almost the same as the median of random weighted averaging. In both years, Egypt has the lowest DVI of about 0.2, followed by Algeria, Tunisia, and Libya (with different order). Somalia is the second most vulnerable country, and Malawi and Ethiopia are also among the high vulnerable countries. Comparing the ranks of countries in the 20 year timeframe, Central African Republic has the most exacerbation, falling from rank 17 in 1995 (with a DVI of 0.55) to the third most vulnerable country in 2015 (with a DVI of 0.7). On the other hand, Rwanda denotes the most progress in drought vulnerability between these two years, with 16 ranks improvement (from 38th to 22nd).

Figure 3-6. Comparison of the DVI calculated using the simple averaging method (green asterisks) and the DVI calculated by the random weighted averaging (boxplots) for 1995 and 2015. In both plots, the countries are ordered according to their DVIs.

Least Drought Vulnerable Countries

The top-three countries with the least DVIs are identified as Egypt, Tunisia, and Algeria, all of which are located at the northern part of the African continent. **Figure 3-7**

shows the component averaged drought vulnerability for the top-3 least drought vulnerable countries during 1990-2015. This period is chosen as it provides data for the majority of factors, which allows reliable quantification of vulnerability for each component. Drought vulnerability of each component is quantified using the component averaging method. It should be noted that the land use component is not considered here as it has only two factors and may not conform to the other components. Radar plots are used to show the results of component averaged drought vulnerability in **Figure 3-7**. In the radar plots, each component is located on one of the angles, and the area of the generated pentagon corresponds to the overall drought vulnerability (i.e. a higher plot area implies higher vulnerability). From **Figure 3-7**, focusing on Egypt (shown in green), the social component has decreased from about 0.7 in 1990s to about 0.4 in 2010s (mainly due to the increase of the human development index), while the *Water* resources component has stayed about 0.4 in all years. All three countries are among the most improved countries in terms of *Health* and *Infrastructure* components. Egypt has lower *Water* resources vulnerability to drought than the two other countries, mainly due to the abundant streamflow received from the Nile River.

Figure 3-7. Radar plots representing drought vulnerability index (DVI) of each component for the top-3 least vulnerable countries in Africa (i.e. Algeria, Egypt, and Tunisia).

Most Drought Vulnerable Countries

Chad, Niger, and Malawi are found to be the most drought vulnerable countries. The first two countries are neighbors and located primarily in central parts of Sahara, and Malawi is a fairly smaller country in southeastern Africa. Again, the radar plots are employed to quantify drought vulnerability of these countries, and the results are shown in **Figure 3-8**. From the figure, Malawi and Niger (plotted in green and red, respectively) indicate improvements for the *Health* component, especially Niger with a continuous decrease of vulnerability from about 0.7 in 1990 to about 0.35 in 2015. On the contrary, Chad (plotted in blue) shows almost no change for the *Health* component, and indicates a vulnerability of 0.7 for it in all years. Furthermore, Chad demonstrates aggravation for the

Social component too. The *Social* component for Chad has raised from 0.55 to about 0.8 during 1995 to 2015. Both Niger and Chad have the highest vulnerability for *Energy and Infrastructure* component among other African countries. For instance, only 8% of Chad's population had access to electricity in 2014. The rate for Niger and Malawi is 14% and 11%, respectively. In general, Malawi has lower drought vulnerability for the *Water* resources component, mainly because it receives above 1000mm/year precipitation, which is much higher than the average precipitation of the other two countries. Having arid climate with low precipitation, Niger and Chad are highly dependent on transboundary water resources with dependency ratios (i.e. the ratio of freshwater received from the sources outside the country borders) of 90% and 67%, respectively (FAO 2016).

Figure 3-8. Radar plots representing drought vulnerability index (DVI) of each component for the top-3 most vulnerable countries in Africa (i.e. Chad, Malawi, and Niger).

Although the water resources component cannot be improved easily and it is primarily dependent on the regional climatic characteristics, the other four components are inter-connected and improving either of them will have positive feedbacks on the rest of the components to some extent. For instance, in order to improve the *Health* component, hospitals and medical centers should be advanced or even established, which in turn improves Infrastructure and Economy, and will have positive impact on society by decreasing the unemployment rate and advancing the human development index (another point of view is that improving any factor requires investment in other factors as well). In fact, many under-developed countries invest in their infrastructure (e.g. power plants and energy sectors, water storage facilities, or railroads) to advance their economy as well as the corresponding invested component.

Progressive and Retrogressive Countries

Figure 3-9 shows three progressive countries (Burkina Faso, Mali and Rwanda) with a decreasing trend of drought vulnerability and three retrogressive countries (Djibouti, Kenya, and Zimbabwe) with an increasing drought vulnerability over time. For each year, drought vulnerability of each component is calculated separately in order to attribute the overall changes of each component. In some cases, the data is limited before 1980s. For instance, the data for *Economy* component (shown in purple) for Mali is not available in 1960. In general, the progressive countries show a decrease in the vulnerability of *Health* component (shown in green). On the contrary, Zimbabwe indicates large increase for vulnerability from the *Health* component in the past decades. It also shows aggravation of

vulnerability to *Social* component, and the accumulation of these two components are the primary reason for its increasing vulnerability, albeit the improvements on the *Water Resources* component (shown in blue). It should be noted that both Zimbabwe and Kenya indicate decreasing drought vulnerability since 2010 mainly for *Economy* and *Infrastructure* components, respectively. Furthermore, Djibouti and Rwanda show considerable decreasing vulnerability to *Water Resources* component.

Figure 3-9. Historical changes of DVI in each component for the most progressive countries with a decreasing trend of DVI (top) and the most aggravating countries with an increasing trend of DVI (bottom).

3.4.2 Change-Point Analysis and Future Projection of DVI

The median DVI from random weighted averaging is chosen as the representative of drought vulnerability, and it is gathered for each country during the historical period to

be utilized for change-point analysis and projecting future DVI. **Figure 3-10** shows the results of the change-point analysis for Lesotho (top) and Nigeria (bottom). A visual inspection of DVI time-series for Lesotho (plot a.) implies that a change-point exists in 1990, whereas for Nigeria (plot d.), no obvious change can be detected. Change-point analysis is employed to statistically inspect for any significant changes in the DVI time-series. The middle boxplots (plots b. and e.) show the CUSUM for the 10,000 bootstrapped resamples, and the line plot indicate the CUSUM for the original DVI time-series. The S_{diff} is calculated for each case, and the histogram of S_{diff} and S_{diff}^0 (corresponding to the original and resampled DVI time-series, respectively) are shown in the right plots. From plot c, a confidence level of 99.23% is found for Lesotho, which is greater than the 95% threshold and indicates that a change has occurred in the DVI timeseries of Lesotho. The peak of the CUSUM for Lesotho (plot b.) has happened in 1985, and thus, 1985 is the last point before the change occurred. Therefore, DVI values of 1990 onward should be used for future projection of DVI in Lesotho. On the other hand, for Nigeria, 88.69% of the bootstrapped DVIs have $S_{diff}^0 < S_{diff}$, and therefore, the test is unable to detect any significant changes in the DVI time-series at 95% confidence level. In general, most of the time-series that indicate a change-point, have one peak in their CUSUM plot (as in plot b.), whereas for the cases without a change-point, there is usually more than one peak (as in plot e.).

Figure 3-10. Change-point analysis for Lesotho (top) indicating a significant change in the DVI time-series, and Nigeria (bottom) without any change point. Plots (a) and (d) show the DVI time-series. Plots (b) and (e) represent the CUSUM results for original DVI (line) and bootstrapped DVI (boxplots), and the distribution of S_{diff}^0 , and S_{diff} are shown in plots (c) and (f).

The change-point is investigated for each country, and a regression function is fitted to each case considering the start year. The functions, start years, and the coefficient of determination (R^2) for each country are presented in **Table 3-1**. In all cases, the power functions resulted in the highest R^2 among others, while meeting the DVI thresholds. In some cases, the DVI shows several variations in the historical period and does not follow a constant direction. For instance, Mozambique shows a decreasing trend during 1990-2000 and an increasing trend after 2000, which makes it difficult to fit a regression model to it. Therefore, it has one of the least R^2 among other countries. Although if the DVI after 2000 is considered for Mozambique, R^2 of 0.95 is achieved. However, such decision will

be an overestimation of vulnerability with a considerable positive slope, ignoring the long-term changes of DVI. In other words, it is not practical to extrapolate for 80 years in future while relying on only 15 years of data. Therefore, at least 30 years of data is employed to project DVI for the future period, and in almost all cases, the projected DVI has accurately captured the long-term trend and direction of drought vulnerability.

Table 3-1. The functions used for projecting future DVI, the starting years (representing no change afterwards), and the coefficient of determination for each case.

No.	Country	Start Year	Function	R ²
1	Algeria	1990	$DVI(t)=0.2153t^{0.0896}$	0.68
2	Angola	1960	$DVI(t)=0.7895t^{-0.123}$	0.68
3	Benin	1980	$DVI(t)=0.7825t^{-0.141}$	0.86
4	Botswana	1980	$DVI(t)=0.4743t^{-0.168}$	0.81
5	Burkina Faso	1970	$DVI(t)=0.8946t^{-0.156}$	0.92
6	Burundi	1985	$DVI(t)=0.7379t^{-0.06}$	0.34
7	Cameroon	1985	$DVI(t)=0.5033t^{0.0241}$	0.97
8	Cent. African Rep.	1990	$DVI(t)=0.5292t^{0.1378}$	0.79
9	Chad	1985	$DVI(t)=0.6825t^{0.0104}$	0.03
10	Rep. Congo	1985	$DVI(t)=0.3996t^{0.1383}$	0.76
11	Côte d'Ivoire	1975	$DVI(t)=0.4955t^{0.042}$	0.46
12	Dem. Rep. Congo	1990	$DVI(t)=0.6449t^{0.043}$	0.42
13	Djibouti	1990	$DVI(t)=0.4701t^{0.0638}$	0.82
14	Egypt	1990	$DVI(t)=0.2409t^{-0.066}$	0.17
15	Equatorial Guinea	1980	$DVI(t)=0.5405t^{-0.155}$	0.68
16	Eritrea	1980	$DVI(t)=0.6045t^{0.0537}$	0.42
17	Ethiopia	1960	$DVI(t)=0.5504t^{0.1097}$	0.78
18	Gabon	1975	$DVI(t)=0.2983t^{-0.028}$	0.11
19	Ghana	1970	$DVI(t)=0.6944t^{-0.122}$	0.75
20	Guinea	1980	$DVI(t)=0.5667t^{0.0539}$	0.74
21	Guinea-Bissau	1965	$DVI(t)=0.6599t^{0.0169}$	0.05
22	Kenya	1975	$DVI(t)=0.6232t^{-0.025}$	0.28
23	Lesotho	1990	$DVI(t)=0.4471t^{0.1752}$	0.91
24	Liberia	1975	$DVI(t)=0.5339t^{0.0797}$	0.64
25	Libya	1975	$DVI(t)=0.3333t^{-0.154}$	0.48
26	Madagascar	1960	$DVI(t)=0.5766t^{0.0462}$	0.45
27	Malawi	1965	$DVI(t)=0.8699t^{-0.083}$	0.88

28	Mali	1990	$DVI(t)=0.6624t^{-0.077}$	0.69
29	Mauritania	1985	$DVI(t)=0.6488t^{-0.113}$	0.88
30	Morocco	1990	$DVI(t)=0.3793t^{-0.13}$	0.87
31	Mozambique	1990	$DVI(t)=0.6647t^{0.0089}$	0.07
32	Namibia	1980	$DVI(t)=0.3756t^{0.0579}$	0.55
33	Niger	1970	$DVI(t)=0.8397t^{-0.092}$	0.72
34	Nigeria	1960	$DVI(t)=0.7798t^{-0.081}$	0.72
35	Rwanda	1980	$DVI(t)=0.8027t^{-0.137}$	0.88
36	Senegal	1990	$DVI(t)=0.5969t^{-0.091}$	0.72
37	Sierra Leone	1965	$DVI(t)=0.626t^{0.0513}$	0.41
38	Somalia	1980	$DVI(t)=0.88t^{-0.109}$	0.67
39	South Africa	1990	$DVI(t)=0.2566t^{0.167}$	0.68
40	Sudan	1965	$DVI(t)=0.5912t^{0.0181}$	0.35
41	Togo	1985	$DVI(t)=0.6674t^{-0.049}$	0.62
42	Tunisia	1990	$DVI(t)=0.2448t^{-0.088}$	0.47
43	Uganda	1970	$DVI(t)=0.7209t^{-0.059}$	0.47
44	Rep. Tanzania	1980	$DVI(t)=0.6405t^{0.0185}$	0.86
45	Zambia	1980	$DVI(t)=0.559t^{0.0702}$	0.43
46	Zimbabwe	1980	$DVI(t)=0.371t^{0.2716}$	0.85

The functions of **Table 3-1** are applied to extrapolate the DVI for the future period of 2020-2100, and the results are plotted along with the historical DVIs. **Figure 3-11** shows the timeseries of DVI for each country during the historical period (1960-2015) and future projections (2020-2100). Focusing on the late 21st century, Egypt, Libya, and Tunisia indicate the least DVIs, and Central African Republic, Ethiopia, and Zimbabwe show the highest drought vulnerability.

Figure 3-11. Temporal variations of Drought Vulnerability Index (DVI) for each country during the historical period of 1960-2015 and future projections of 2020-2100.

Results of **Table 3-1** and **Figure 3-11** demonstrate that the number of countries showing decreasing, increasing, and no considerable change in DVI are 19, 13, and 14, respectively. In order to better understand the overall pattern of DVI through time, violin

plots (Hintze and Nelson 1998) are used and the distribution of DVI in each year is investigated. **Figure 3-12** shows the distribution of DVIs for the 46 African countries in each year for the historical period (plotted in green) and future projections (plotted in blue). The red plus signs in the figure indicate the median of DVI in each year. As it can be inferred, in the 2000s (when the number of factors used are considerably higher than before) the distribution is highly skewed having one peak above 0.6 and a smaller peak around 0.5. There is also a small group of countries that have DVI values less than 0.4. However, the distribution is considerably changed by 2080s, with both parts growing and two peaks found; one peak for the DVIs less than 0.4, and one peak around the median for the DVIs ranging between 0.4-0.8. In other words, during 1995-2015, the countries can be classified to two groups of low vulnerable ($DVI < 0.4$) and moderate-to-high vulnerable ($0.5 < DVI < 0.8$). Whereas in 2090s, three groups of countries are identified as low vulnerable ($DVI < 0.35$), moderate vulnerable ($0.35 < DVI < 0.6$), and high vulnerable ($DVI > 0.6$). Furthermore, almost no country had DVIs less than 0.2 or above 0.8 during 1995-2015. Whereas, the distribution of DVI is much wider after 2070s, and several countries indicate extremely high and extremely low drought vulnerability. In general, the median DVI shows a slightly increasing trend during the historical period and it seems to be slightly decreasing over time for the future projections.

Figure 3-12. Violin plots representing the DVI distribution of the 46 African countries for historical simulations (green) and future projections (blue). The red plus (+) signs indicate the median of DVI in each year.

The projected DVIs should be considered for long-term assessments and not for short-term changes. In other words, DVI projections provide probable simulations of future drought vulnerability in each 5-year period, whereas they should be implemented for multi-decadal analysis. This is somehow similar to the application of Global Climate Models (GCMs) for climate change studies, in which the models provide daily simulations, while their primary purpose is mainly for long-term assessments (Ahmadalipour et al. 2017b).

3.4.3 Evaluating DVI estimates

The calculated drought vulnerability index should be evaluated in order to reveal its reliability for further applications in drought risk management and adaptation planning. Two main sources are utilized for the evaluation purposes: 1) the previous assessments of

drought vulnerability, and 2) the historical observed drought impacts. A large-scale national-level assessment of drought vulnerability in Africa was employed by Naumann et al. (2014), which is a static investigation and it did not investigate the temporal variations of vulnerability. The results of this study have been used as the former source of evaluation. For the latter, the International Disaster Database (EM-DAT) and the review of droughts in Africa carried out by Masih et al. (2014) were utilized to perform a descriptive and qualitative evaluation of the estimated DVI.

Naumann et al. (2014) found Somalia, Burundi, Niger, Mali, Ethiopia, and Chad as the top-6 most vulnerable countries to drought with DVIs higher than 0.6. The current study confirms it for most years, and the top-3 most drought vulnerable countries of this study are among those identified before. Furthermore, Naumann et al. (2014) identifies Egypt as the least vulnerable country, which is similar to our assessment, followed by Tunisia and Gabon, both of which are among the low drought vulnerable countries in our findings. The spatial pattern of DVI in both studies seem to be similar, with few differences. For instance, this study characterizes Libya among the least vulnerable countries, whereas Naumann et al. (2014) classifies it as a moderate country, mainly due to its deficiencies in renewable natural resources component.

Considering the drought impacts and damages, the 2010-2011 drought of the Horn of Africa affected over 12 million people (Zaitchik et al. 2012; Dutra et al. 2013). During 1960-2012, droughts in Ethiopia and Somalia affected more than 66 million and 13 million people, and resulted in mortality of over 400,000 and 100,000 people, respectively (Masih et al. 2014). Therefore, it can be concluded that Somalia and Ethiopia are highly vulnerable

to drought. The number of affected people and the total mortality caused by drought is over 30 million and 150,000 for Sudan, and over 5.5 million and 3000 for Chad, respectively. The numbers are extremely high considering the total populations of 27 million and 8 million (in 2005) for Sudan and Chad, respectively. The values are similar for Niger (23 million and 85,000) indicating high drought vulnerability. On the other hand, over 17 million people have been affected by droughts in South Africa during 1960-2015, none of whom were killed (Vogel et al. 2010). In general, droughts in northern and southern parts of Africa have higher economic damages, whereas in central parts, many people have been affected and killed by droughts in the past.

This section provided a comprehensive assessment of drought vulnerability at a national level across the African continent. The future drought vulnerability projections was calculated based on a statistical analysis of the historical relative changes of the African countries' drought vulnerabilities. Therefore, although it provides probable estimates of future vulnerability, it is not a numerical simulation forecast, and it should be applied for long-term assessments. Forecasting the future drought vulnerability is an extremely complicated challenge, which is dependent on numerous sectors having dynamic feedbacks on each other. For instance, growing population is a serious issue in the undeveloped African countries, which is expected to impose severe impacts on food security and social development (Godfray et al. 2010; Hanjra and Qureshi 2010; Tomlinson 2013; Khan et al. 2014). Moreover, climate change will alter the seasonal cycle of the hydrologic system, which will in turn significantly affect the water resources component of vulnerability (Leichenko and O'brien 2002; Sowers et al. 2011; IPCC 2014). It will also

impact the agricultural productivity and food security (Fischer et al. 2002; Mougou et al. 2011; Wheeler and Von Braun 2013). Apart from the impacts on the natural resources, societal instability, conflicts, wars, and diseases may considerably impacts the socio-economic components of a region, causing abrupt changes in the drought vulnerability (Scheffran et al. 2012).

3.5 Summary and Conclusion

This section presented a comprehensive assessment of drought vulnerability across Africa using a composite Drought Vulnerability Index (DVI) for the historical period of 1960-2015. Vulnerability was quantified at a national level using 28 factors from six components of economy, energy and infrastructure, health, land use, society, and water resources. All the factors were diagnosed for dependency using multi-collinearity tests, and various weighting methodologies were implemented to calculate DVI. A change-point analysis was conducted for the DVI of each country, and the calculated DVIs were then projected into the future period of 2020-2100. The main findings of the study are as follows:

- The least vulnerable countries to drought are Egypt, Libya, Tunisia, and Algeria (all located in northern parts of Africa) and South Africa.
- The most vulnerable countries to drought are Chad, Malawi, Niger, and Somalia, all of which are highly vulnerable to energy and infrastructure component.

- Burkina Faso, Mali, and Rwanda indicate improvements for drought vulnerability with a decreasing DVI and progressive health components. On the other hand, Djibouti, Kenya, and Zimbabwe show increasing DVI over time.
- In general, the median DVI of African countries shows slightly decreasing trend in future projections. Meanwhile, a considerable number of countries are expected to become extremely vulnerable to drought, with $DVI > 0.8$.
- Central African Republic, Ethiopia, Lesotho, and Zimbabwe will be among the most vulnerable countries in the late 21st century. The least vulnerable countries in future are expected to be the same as in historical period.

4 Drought Hazard and Risk in Africa

4.1 Background

Drought risk is generally characterized as a function of three primary components: (i) hazard that is the possible future occurrence of drought, (ii) vulnerability that is the susceptibility of exposed elements to the adverse effects of drought, and (iii) exposure that is the population and assets affected by drought (Blauhut et al. 2015b; Han et al. 2016). Drought risk refers to the potential losses from a particular hazard imposed by a drought event (Brooks et al. 2005; Cardona et al. 2012). In other words, drought risk is determined not only by the intensity of the event and the amount of exposure, but also by the vulnerability of the society at a given time (Birkmann 2007; Carrao et al. 2016).

Reactive approaches are still used for drought management in most parts of the world, which is commonly referred to as crisis management, responding to the impacts that have already occurred (Wilhite et al. 2014; Svoboda et al. 2015). Nevertheless, these approaches are known to be untimely and disintegrated, and thus, previous drought management attempts have usually been ineffective with a rise in the socioeconomic impacts of drought (Peterson et al. 2013; Sivakumar et al. 2014). The scientific consensus has pointed out the necessity to move from reactive to proactive risk management strategies (Birkmann et al. 2013; Rossi and Cancelliere 2013).

Climate change and the anthropogenic global temperature rise will have significant impacts on natural hazards, extreme events, economy, and health (Honda et al. 2014; Ahmadalipour et al. 2017b; Gergel et al. 2017). Multitude of studies have investigated the

impacts of climate change on drought for various regions of the globe (Zhao and Dai 2016; Ahmadalipour et al. 2016). It has been concluded that climate change will intensify drought in many regions across the world (Ahmadalipour et al. 2017a). This is especially more considerable in arid regions (e.g. Northern Africa) as global warming will increase the potential evapotranspiration (Asadi Zarch et al. 2014; Touma et al. 2015).

Besides the severe impacts of climate change on the African continent, population growth is also expected to augment the natural resources scarcity and food insecurity (Godfray et al. 2010; Seto et al. 2012; Khan et al. 2014). Population growth affects drought risk both directly, i.e. through increasing the exposure component of the risk, and indirectly, i.e. by altering the vulnerability components. It is a grand challenge in Africa, especially for the least developed countries, and it will be a huge burden for the social and human development (Hanjra and Qureshi 2010; Antwi-Agyei et al. 2012).

Despite the increasing concerns regarding the escalating impacts of droughts on food, energy, and water resources in the 21st century, it has been argued that more attention has been given to studying drought hazard rather than providing consistent drought risk assessment frameworks (Shiau and Hsiao 2012; Kim et al. 2015; Tánago et al. 2016). In fact, many of the recent studies that claim to assess “drought risk” have actually studied the probability of drought hazard, ignoring the vulnerability and exposure components of risk (e.g. Kam et al. 2014; Cook et al. 2015; Diffenbaugh et al. 2015).

The combination of climate change, population growth, and the aggravation of socioeconomic vulnerabilities will intensify drought hazard, exposure, and vulnerability in many regions of Africa. It will in turn substantially increase drought risk across the

continent. Therefore, it is important to investigate the changes of each component of risk separately and understand their cumulative impacts on drought risk. The current study is the first comprehensive and multi-dimensional assessment of the compounding effects of climate change, population growth, and vulnerability changes on drought risk over Africa. Drought risk is assessed at a national scale for the historical as well as future periods, and its decadal changes are investigated for each country. The results will provide long-term projections of drought risk and will reveal the role of each component (hazard, vulnerability, and exposure) in each country, which will be beneficial for strategic planning and adaptation policy making over the continent.

4.2 Data

Three different types of data are used to address the three components of risk (i.e. hazard, vulnerability, and exposure). Vulnerability assessment has been thoroughly explained in the previous chapter. For quantifying the hazard, Regional Climate Models (RCMs) developed by the Coordinated Regional Climate Downscaling Experiment (CORDEX) are utilized over the African domain, i.e. AFR-44 (Jones et al. 2011). Precipitation (Prec) and potential evapotranspiration (PET) are acquired from 10 RCMs at a daily timescale and 0.44° spatial resolution for the entire African continent during the historical period of 1951-2005 as well as two future scenarios of RCP4.5 (representing moderate emission increase in future) and RCP8.5 (representing business as usual scenario) for the period of 2006-2100. The data are then accumulated to monthly timescale to be

employed for drought analysis. More information about the RCMs used in this study are presented in **Table 4-1**.

Table 4-1. The 10 RCMs used in this study and their characteristics. All the RCMs are developed by the Swedish Meteorological and Hydrological Institute (SMHI) and have a spatial resolution of 0.44° .

No	Deriving GCM	Original Modeling Institute	Original Resolution (lat $\times$ lon)	Ens. Member
1	CanESM2	Canadian Centre for Climate Modeling and Analysis	$2.8^\circ \times 2.8^\circ$	r1i1p1
2	CNRM-CM5	National Centre of Meteorological Research, France	$1.4^\circ \times 1.4^\circ$	r1i1p1
3	CSIRO-Mk3-6-0	Commonwealth Scientific and Industrial Research Organization, Australia	$1.8^\circ \times 1.8^\circ$	r1i1p1
4	EC-EARTH	EC-EARTH consortium	$1.0^\circ \times 1.0^\circ$	r12i1p1
5	GFDL-ESM2M	Geophysical Fluid Dynamics Laboratory	$2.5^\circ \times 2.0^\circ$	r1i1p1
6	HadGEM2-ES	Met. Office Hadley Centre	$1.88^\circ \times 1.25^\circ$	r1i1p1
7	IPSL-CM5A-MR	Institut Pierre-Simon Laplace	$2.5^\circ \times 1.25^\circ$	r1i1p1
8	MIROC5	Atmosphere and Ocean Research Institute (The University of Tokyo), National Institute for Environmental Studies, and Japan Agency for Marine-Earth Science and Technology	$1.4^\circ \times 1.4^\circ$	r1i1p1
9	MPI-ESM-LR	Max Planck Institute for Meteorology (MPI-M)	$1.9^\circ \times 1.9^\circ$	r1i1p1
10	NorESM1-M	Norwegian Climate Centre	$2.5^\circ \times 1.9^\circ$	r1i1p1

Lastly, exposure is investigated using human population data for each African country. The population data are acquired from United Nations (2015) and utilized for the historical period of 1950-2015 as well as three future population projection scenarios of low, medium, and high variant over the period of 2015-2100.

4.3 Methodology

The risk formulation employed in this study is the same as that implemented by the United Nations International Strategy for Disaster Reduction (UNISDR 2015) and the

Intergovernmental Panel on Climate Change (IPCC 2012), and it has been utilized in multitude of earlier assessments (Peduzzi et al. 2002, 2009; Cardona et al. 2012; Carrao et al. 2016). It is defined as:

$$Risk = Hazard \times Exposure \times Vulnerability \quad 4-1$$

As mentioned in the data section, the population of each county is used as exposure, and a comprehensive multi-dimensional framework was carried out to quantify vulnerability at a national level. Drought hazard is quantified using the Standardized Precipitation Evapotranspiration Index (SPEI) (Vicente-Serrano et al. 2010). SPEI is a multi-scalar drought index that accounts for temperature effects on drought and it has been employed in numerous studies (Li et al. 2015; Touma et al. 2015; Ahmadalipour et al. 2016, 2017a). It is based on a climatic water balance and considers the water deficit as the difference between precipitation and potential evapotranspiration ($D = P - PET$). The water deficit (D) can be calculated at different accumulation periods to reflect the variations at different timescales. In this study, D is calculated for each grid (at 0.44-degree spatial resolution) and each month, and then accumulated to 12-month timescale in order to capture the long-term impacts of climate change as suggested by previous studies (Ahmadalipour et al. 2017a). The nonparametric Weibull plotting position is utilized to calculate the SPEI as follows:

$$P(X_i) = \frac{i}{n + 1} \quad 4-2$$

where i is the rank of D from smallest to largest, n is the sample size, and $P(X_i)$ denotes the empirical probability. $P(X_i)$ is then transformed to the standard normal

distribution (with zero mean and unit standard deviation) which will be the corresponding value of the SPEI:

$$SPEI = \Phi^{-1}(P) \quad 4-3$$

The SPEI is calculated separately for each month, and the monthly values are arranged to obtain the time-series of drought index. A zero value for SPEI indicates no drought condition and negative values represent an imbalance in the available water, indicating dry conditions. The lower the value of SPEI, the higher is the intensity of drought.

The SPEI-12 is calculated for each grid of each RCM for the historical period of 1951-2005 and two future scenarios of RCP4.5 and RCP8.5 during 2006-2099. The calculated SPEI is at 0.44-degree spatial resolution. A Hazard Index is proposed and utilized to quantify drought hazard at national scales. After calculating the intensity of drought for each month using the SPEI, drought hazard of a particular month in a country will be calculated by averaging the negative SPEI values across the country divided by the total number of grids of that country. Then, the annual drought hazard will be the mean of monthly drought hazards as follows:

$$Hazard\ Index = \left| \sum_{i=1}^{12} \sum_{n=1}^N SPEI(< 0) / 12 \cdot G \right| \quad 4-4$$

where i indicates the month, N denotes the number of grids in the country that experience drought in a particular month, and G is the total number of grids that cover the country. The drought hazard calculated by the above function will have the same absolute

range as the SPEI (i.e. $0 < \text{Hazard Index} < \sim 2.2$). It reflects the overall severity of drought in a particular region. For instance, if half of a country experiences moderate drought (SPEI = -1) for 6 months in a year and no drought for the rest of the year, the calculated Hazard Index will be $0.25 (1 \times 0.5 \times \frac{6}{12} = 0.25)$. The maximum Hazard Index is observed when the entire region experiences extreme drought (SPEI < -2) for the entire year. Therefore, the proposed Hazard Index is a compound indicator of the intensity, duration, and extent of drought.

After quantifying hazard, vulnerability, and exposure of each country, drought risk is also quantified at national scale. For each country, drought risk is quantified for the historical period for each RCM, and a historical mean drought risk value is calculated for each RCM by averaging the corresponding drought risk values during the period of 1975-2005. This 30-year period is chosen since it provides more accurate data than the antecedent years (especially the socio-economic data for quantifying vulnerability). Similar procedure is implemented to calculate drought risk projections in near future (2010-2040), intermediate future (2040-2070), and distant future (2070-2100).

After calculating drought risks for historical and future periods, the changes in drought risk are assessed by comparing the projected risk scenarios with the simulated historical drought risk. Risk ratio is calculated for each country as follows:

$$\begin{aligned} \text{Risk Ratio}_{m,r,p} &= \frac{\text{Risk}_{fut;m,r,p}}{\text{Risk}_{hist;m}} \\ &= \frac{\text{Hazard}_{fut;m,r}}{\text{Hazard}_{hist;m}} \times \frac{\text{Exposure}_{fut;p}}{\text{Exposure}_{hist}} \times \frac{\text{Vulnerability}_{fut}}{\text{Vulnerability}_{hist}} \end{aligned} \quad 4-5$$

where *hist* and *fut* indicate the values for historical and future periods, respectively. m, r, and p denote different permutations of climate model (RCMs), climate scenarios (RCPs), and population scenarios, respectively. This has been performed for each country for the three future periods. **Figure 4-1** shows a schematic diagram of the risk components utilized in this study during historical and future periods.

Figure 4-1. Schematic diagram of the risk analysis methodology employed in this study and its different components in historical and future periods.

The changes of each component of risk are also studied along with the overall changes of drought risk ratio. Future drought risk ratio is quantified for each African country (46 countries) using 10 RCMs, 2 climate scenarios (RCP4.5 and RCP8.5), 3 population scenarios (low, medium, and high variability), and three 30-year future periods (near, intermediate, and distant future), totaling 8280 drought risk scenarios across the continent ($46 \times 10 \times 2 \times 3 \times 3 = 8280$). This makes it possible to probabilistically assess future drought risk conditions and characterize the uncertainties associated with different sources.

Besides the national-scale Hazard Index and drought risk, two important characteristics of drought hazard are investigated at grid-scale (0.44° spatial resolution): the spatial extent of drought and drought intensity. Drought extent is calculated by detecting the area of Africa affected by drought (i.e. $\text{SPEI} < -0.8$; Chen et al., 2012) divided by the total area of the African continent. Moreover, the long-term linear trends of drought intensity are assessed for each grid during the future period of 2005-2100. The Mann-Kendall trend test, as a rank-based non-parametric test and independent of the statistical distribution, is utilized to investigate the significance of trends (Kendall 1948).

4.4 Results and Discussion

The results for drought vulnerability assessment and projection were exclusively explained in previous chapter. Here, the results of the other components of risk (i.e. drought hazard and exposure) are thoroughly investigated, followed by the results and discussion for drought risk. Drought hazard is investigated at both grid- and national-scale, whereas the other components (vulnerability and exposure) and hence the drought risk are quantified at a national-scale.

4.4.1 Drought Hazard

Figure 4-2 shows the spatial extent of drought across Africa calculated from the SPEI-12 results for the historical period (shown in grey) as well as two future scenarios of RCP4.5 and RCP8.5 (shown in blue and red, respectively). The shaded area indicates the results of 10 RCMs, and the lines represent the ensemble mean drought extent of the

corresponding scenario. The figure shows that the historical mean dry area over Africa is about 7%, and it increases to about 25% in the late 21st century. Slightly increasing dry extent is detected during the historical period, especially after 1990s. The drought extent projections of RCP4.5 and RCP8.5 are similar until the 2030s, with the latter showing higher dry area afterwards.

Figure 4-2. Spatial extent of historical and future droughts across Africa based on the SPEI-12 results. The shaded area represents the results from 10 RCMs and the lines indicate the ensemble mean dry area for each corresponding concentration pathway.

The long-term future trends of SPEI-12 is calculated for each RCM over the period of 2005-2100, and the results are shown in **Figure 4-3**. The figure shows the mean decadal change of SPEI for RCP4.5 (top) and RCP8.5 (bottom). A negative trend value indicates decreasing SPEI and thus increasing intensity of drought. The Mann-Kendall trend test is utilized to investigate the significance of trends at 0.05 significance level, and the negative

trends (intensifying drought conditions) that are significant (yielding a p-value less than 0.05) are plotted in the figure. Most of the RCMs indicate significantly increasing drought intensity for northern and southern parts of Africa. It should be noted that a decadal trend value of -0.2 (shown in red color) results in substantial increase of drought intensity, as it means that in 25 years (2.5 decades) the average SPEI value will decrease by 0.5 ($-0.2 \times 2.5 = -0.5$). It implies that drought intensity is expected to be exacerbated by one category, given the SPEI thresholds of -1, -1.5, and -2 representing moderate, severe, and extreme drought conditions, respectively (Dai 2012; Ahmadalipour et al. 2016). In general, results of both RCPs show similar spatial patterns, with RCP8.5 indicating more severe droughts. For instance, the RCP4.5 models show trend values of less than -0.15 for most regions, whereas results of RCP8.5 indicate trends twice as much in many regions. The results of **Figure 4-3** are in agreement with previous assessments using other drought indices such as the Palmer Drought Severity Index (PDSI) (Dai 2012), Supply–Demand Drought Index (SDDI) (Touma et al. 2015), and Reconnaissance Drought Index (RDI) (Asadi Zarch et al. 2014).

Figure 4-3. Long-term trend of SPEI-12 for the future period of 2005-2100 for each RCM in RCP4.5 (top) and RCP8.5 (bottom). The Mann-Kendall trend test is used at 0.05 significance level and only the significantly negative trends are plotted.

The Hazard Index (Equation 4-4) is calculated for the 10 RCMs for each country during the historical as well as future periods, and the results are shown in **Figure 4-4**. The figure shows the temporal changes of Hazard Index and the associated model and scenario uncertainties. The historical, RCP4.5, and RCP8.5 results are plotted in grey, blue, and red, respectively, with the shaded area showing the results of 10 RCMs and the lines representing the ensemble mean results. The projections of Hazard Index show different patterns and diverse uncertainties in different countries. In general, the northern African countries (i.e. Algeria, Egypt, Libya, Morocco, and Tunisia) indicate an increasing Hazard Index during the historical period, all of which demonstrate aggravating future Hazard Index as well. The countries located at the southern parts of Africa (i.e. Botswana, Namibia, South Africa, and Mozambique) follow similar yet moderate increasing patterns. On the other hand, the western African countries below the Sahel region (i.e. Côte d'Ivoire, Guinea, Liberia, and Sierra Leone) do not indicate any significant changes in the Hazard Index of neither the historical period nor the future projections, and the Hazard Index of the two future scenarios are similar for these countries. For other countries, RCP8.5 indicates higher Hazard Index than RCP4.5. The worst drought hazard conditions are expected to happen in Egypt and Libya, both indicating substantial increase of Hazard Index. Egypt is also the country with -the lowest model uncertainty (the narrowest shaded area), especially for the RCP8.5 scenario.

Figure 4-4. Temporal variations of the annual Hazard Index for each country in Africa during the historical period as well as two future scenarios of RCP4.5 and RCP8.5. The shaded areas represent the results of 10 RCMs and the lines indicate the ensemble mean.

In order to better understand the overall changes of drought hazard over Africa, the Hazard Index of each RCM is averaged in 5-year periods for each country, and the distribution of the Hazard Index among the African countries is plotted using violin plots

(Hintze and Nelson 1998). This is done for the historical and future periods, and the results are shown in **Figure 4-5**. The colors used are consistent with the previous figures. The plus signs (+) indicate the median of distribution in each case. The figure shows that the Hazard Index has generally increased during the historical period, and it is expected to substantially increase in future. The median of Hazard Index is below 0.5 in the historical period, and it is projected to become twice as much in the distant future. The two future RCPs have similar distributions in near future (until 2040s), whereas RCP8.5 generally projects higher values afterwards.

Figure 4-5. Violin plots showing the distribution of the Hazard Index among the African countries for historical and future periods. The plus signs (+) indicate the median Hazard Index in each case.

4.4.2 Exposure

Figure 4-6 shows the annual population projection of each country as well as the total population of the African continent during the historical period (shown in grey) and three future scenarios of low, medium, and high variant (shown in green, yellow, and red,

respectively). In general, the majority of African countries are expected to experience vast expansion in their population in the upcoming decades. This can be realized by considering the results for Total Africa (the last subplot in **Figure 4-6**) where the population of Africa at the end of 20th century was about 1 billion people, whereas it will increase to 3, 4.5, and 6 billion people by the end of the 21st century for low, medium, and high variant scenarios, respectively. This unprecedented population will impose serious challenges for Africa regarding social development, food security, health, and many other sectors (Vörösmarty et al. 2000; Gerland et al. 2014; Schlosser et al. 2014). The most population increase rate is found in Niger and Chad (neighboring countries located at the sub-Saharan region), both among the highly vulnerable countries in terms of the social and human development components (Neumayer 2001). For instance, Niger's population was about 10 million people in the 2000s, and it is expected to increase to 150-250 million people by 2100s; a 1500-2500% increase rate. Considering the limited economic and natural resources of the country due to its geopolitical location and the arid climate of the region, the vast population increase will have substantial effects on drought risk with devastating socioeconomic impacts on the country. On the contrary, Libya, Morocco, and Tunisia (all of which are located at the northern parts of the African continent) show the least population change rate, indicating decreasing population for the low variant scenario. These three countries are also among the least drought vulnerable countries in Africa.

Figure 4-6. Historical record and projected population of each country in the African continent. The last subplot shows the total population of the African continent. The y-axis in all subplots is in million people, except for the last subplot (Total Africa) which shows the population in billions.

4.4.3 Drought Risk

Drought risk ratio (Equation 4-5) is calculated in each country for 10 RCMs, 3 population scenarios, and 2 representative concentration pathways during the future

periods of 2010-2040, 2040-2070, and 2070-2100. **Figure 4-7** shows the risk ratio projections of each country for low and high variant population scenarios (the medium variant scenario is not shown in the figure to have a clearer representation). The three periods are shown in distinct colors, and the order of all subplots are consistent as identified in the bottom row plots. In each plot, boxplots are used to show the risk ratio of 10 RCMs and the red dash in the middle of each box represents the median of 10 RCMs. The figure shows that the lowest risk ratio is found in Tunisia, Morocco, and Libya, respectively, all of which are located at the northern parts of Africa. Despite the substantial increase of drought hazard in these three countries, all of them indicate decreasing vulnerability and low changes in exposure. For instance, for the case of low variant population scenario, the exposure is expected to decrease in these countries, thus keeping the risk ratio at almost constant rates in the future periods, despite the significant increase of drought hazard. Nonetheless, even in most moderate cases, the drought risk is expected to become 2-3 times higher than that in the historical period. On the contrary, Niger and Chad demonstrate the highest risk ratios.

Figure 4-7. Boxplots showing the drought risk ratio of each country in the African continent for 10 RCMs, two climate pathways (RCP4.5 and RCP8.5) and two population scenarios (Low and High Variant). The red dash in the middle of each plot indicates the median of the 10 RCMs.

Considering the drought risk ratios of near future (plotted in cyan in **Figure 4-7**), all scenarios show similar ranges in each countries. Whereas in distant future (brown plots

in **Figure 4-7**), the exposure proves to have significant effects on the risk ratio, even more influential than the climate pathway in many cases. For instance, the distant future drought risk ratio (brown boxplots) of *High Var.-RCP4.5* is higher than that for *Low Var.-RCP8.5* in most countries. In order to better understand the risk ratios and their differences in various scenarios, the ensemble mean drought risk ratio of each African country is shown in **Figure 4-8** for all the future scenarios. The figure shows that in several cases, the *High Var.-RCP4.5* drought risks are even greater than the *Med. Var.-RCP8.5* risks in distant future. Moreover, the combination of higher concentration pathway (RCP8.5) and high variant population scenario in intermediate future (2040-2070) leads to risk ratios as large as a moderate condition (*Low Var.-RCP4.5*) in distant future (2070-2100). In other words, if no adaptation/mitigation planning is followed for climate emissions and population, it will accelerate the devastating risks to happen decades sooner.

The spatial patterns of the projected drought risk ratios can be understood from **Figure 4-9** which shows the risk ratios in near and distant future periods. The figure shows that the central African countries should expect higher risk ratios than the southern and northern African countries. The spatial patterns are somehow similar to those for drought vulnerability in Africa (Naumann et al. 2014). In general, the southern and northern African countries are more industrialized, having access to more resources and thus indicating lower socioeconomic vulnerabilities and higher social development. This will in turn be effective for their future population projections, keeping the exposure at mediocre levels for the majority of those countries (Gerland et al. 2014).

Figure 4-9. Spatial distribution of the projected drought risk ratios in the African countries for all scenarios in near and distant future.

In order to understand the overall changes of drought risk ratio across the African continent, the distribution of the risk ratio among 46 African countries is plotted for each future period/scenario using the violin plots, and the results are shown in **Figure 4-10**. The plus signs (+) indicate the median of each plot. The figure clearly shows the overall changes of drought risk in different scenarios. The median of drought risk ratio is about 4 in near future, whereas it increases to about 10 in intermediate future, and reaches to 9-19 in distant future. The difference between the different scenarios is negligible in near future, whereas disparities are found among them in distant future. In fact, the highest risk ratio of the optimum (most favorable) scenario (*Low Var.-RCP4.5*) is about the same as the median of the worst-case scenario (*High Var.-RCP8.5*), which reflects the importance of climate and population planning and management.

Figure 4-10. Violin plots representing the distribution of the drought risk ratio among the African countries for the future periods/scenarios. The plus signs (+) indicate the median risk ratio in each case.

The results implicate that the controlling component of drought risk is different for each country. In some countries (e.g. Niger) the population increase seems to be the main challenge for drought risk, which is accompanied by intensifying hazard conditions. Since drought risk formulation is an integration of hazard, exposure, and vulnerability, it is necessary to decompose it and assess the role of each component on drought risk. **Figure 4-11** shows the change rates of each component in each country for near and distant future. For instance, the change rate of vulnerability is calculated as $\frac{Vulnerability_{fut}}{Vulnerability_{hist}}$. The figure shows the mean change rate from the multiple available scenarios of hazard and exposure. In **Figure 4-11**, the countries are arranged in descending order of drought risk ratio from the highest to lowest (it should be noted that multiplication of the component yields the risk, and not the summation of them). In each component, a change rate lower than 1 indicates a decreasing trend, which is in favor of decreasing drought risk. This is found to be true in several countries, e.g. Egypt, Morocco, and Tunisia indicate vulnerability rates of about half the historical period. Focusing on the hazard change rates, Liberia shows the lowest rate with a slightly decreasing hazard for both near and distant future, whereas all other countries show increasing hazard trends with varied ranges.

Figure 4-11. Decomposition of the drought risk components and their changes compared to the historical period. The figure shows the mean change rates among various scenarios and the countries are arranged in descending order from the highest to lowest risk ratios.

Figure 4-11 clearly identifies the difference between hazard and exposure change rates. For instance, in near future, most of the countries indicate similar change rates for

hazard and exposure, except for the northern African countries (i.e. Algeria, Egypt, and Morocco) having hazard change rates higher than that of exposure, and the central African countries (i.e. Burundi, Equatorial Guinea, and Rwanda) where exposure change rate is greater than hazard rates. For distant future however, the majority of countries indicate significantly higher exposure change rates than hazard rates, which reflects the impacts of population growth on drought risk. Comparing the countries' overall rank between near and distant future, the few top and low countries are the same in both periods. Djibouti shows the highest relative improvement of drought risk ratio from the near future (ranked 36th among African countries) to distant future (ranked 13th among African countries). On the other hand, Burundi is ranked 26th among all African countries in near future, and it is dropped to rank 38th in distant future. In both of these countries, the changes in exposure has an important role for mitigating or aggravating the relative order of a country's drought risk ratio.

The present study provided a comprehensive assessment of the projected drought risk across Africa by means of an integrated drought risk framework based on hazard, exposure, and vulnerability. The spatial patterns of drought risk results of this study are consistent with the earlier assessments (Kiguchi et al. 2015; Veldkamp et al. 2016). Brooks et al. (2005) classified the sub-Saharan African countries among the most vulnerable to climate hazards in the world. Carrao et al. (2016) assessed the current state of global drought risk and found the vulnerability and risks of the southern African countries lower than the central African nations. Several other studies indicate similar spatial patterns for the impacts of climate change on drought hazard and water scarcity projections (Sheffield

and Wood 2008; Hanasaki et al. 2013; Schewe et al. 2014; Gosling and Arnell 2016; Liu et al. 2017).

Drought and water scarcity are among the severe challenges affecting the world, and climate change and population growth will exacerbate them (Hirabayashi et al. 2008; Jaeger et al. 2013; Mekonnen and Hoekstra 2016). The issue is of higher concern for Africa, where the majority of countries experience deficiency in natural and economical resources (Neumayer 2001). Results of this study identified increasing drought risk for the entire African continent, with the central African countries indicating the most severe aggravation. The results indicate that controlling the population growth can improve the vulnerability and decrease potential exposure, which will in turn significantly mitigate drought risk. Meanwhile, reducing net emissions to limit the global warming and climate change will substantially decrease drought risk, especially in distant future (Gudmundsson and Seneviratne 2016; Chen and Sun 2017). According to recent assessments, it is still feasible to limit the global warming to less than 2°C compared to the pre-industrialized era (Millar et al. 2017), albeit it is unlikely to achieve it (Raftery et al. 2017). Therefore, the sooner climate change mitigation planning is started, the higher is the chance to reduce its associated risks.

4.5 Summary and Conclusion

This chapter provided the first comprehensive centennial assessment of drought risk over Africa considering the components of hazard, exposure, and vulnerability. An ensemble of 10 spatially fine-resolution CORDEX regional climate models (RCMs) were

utilized for two future concentration pathways of RCP4.5 and RCP8.5 to quantify drought hazard. Furthermore, three different population projection scenarios were employed to characterize the exposure. Therefore, drought risk is quantified using a multi-model and multi-scenario approach capable of characterizing the uncertainties at different levels. The spatiotemporal trends and changing patterns of the drought risk and its components were investigated, and the main findings of the study are as follows:

- Drought risk will increase in future for the entire African continent. The change rates are higher for the central African countries compared to the southern and northern African countries.
- Although different future scenarios indicate similar results in near future, vast differences are found between the moderate and extreme scenarios in distant future.
- Niger and Chad indicate the highest risk ratios among other African countries compared to the historical period. Their tremendous drought risk ratios are attributed mainly to their considerable population growth as well as the augmented drought hazard due to global warming.
- Tunisia and Morocco indicate the lowest risk ratio, albeit their drought hazard increase. This is mainly due to their advanced socioeconomic sectors, which stabilizes the population and decreases drought vulnerability.
- Population growth is a serious concern in Africa, as the majority of African countries are already dealing with lack of natural and financial resources, and it will

further aggravate their social development and exacerbate drought risk in the continent.

The results demonstrated the significant impacts of climate change and population growth on drought risk across Africa, and corroborated the urgency for climate adaptation planning and social development in the continent.

5 Climate Change and Heat-Related Mortality Risk

5.1 Background

Studies have reported that even if the global mean temperature increase is limited to 2°C, warming over land will be far beyond 2°C in many regions. Global climate change will increase the frequency of heatwaves and extreme high temperatures in various regions (Fischer and Knutti 2015). The social impacts of climate change and extreme temperatures received higher attention after the 2003 European heatwave caused high mortality (Christidis et al. 2015; Li et al. 2016). For instance, several studies assessed the impacts of climate change on labor capacity (Dunne et al. 2013; Zhao et al. 2016). It has been shown that anthropogenic warming has already prolonged the heatwaves and increased their frequency in various locations of the world (Sun et al. 2014b). The severe heatwaves of Texas in 2011 (Luo and Zhang 2012), Australia in 2012 (Lewis and Karoly 2013), and Egypt in 2015 (Mitchell 2016) were all associated with large spatial extent and prolonged duration.

In the Middle East and North Africa (MENA), the anthropogenic warming is strongest in summer; whereas elsewhere it is usually stronger in winter (Lelieveld et al. 2016; Waha et al. 2017). Considering the hot arid climate of the region, the morbidity and mortality risk of extreme high temperatures is one of the grand challenges facing human health and society (Russo et al. 2016). Pal and Eltahir (2016) showed that climate change will increase the air temperature across the Middle East to thresholds not tolerable for human body, especially around the Persian Gulf. Schär (2016) discussed that the

temperature has already exceeded the safe threshold in some humid locations of the Persian Gulf (e.g. Bandar Mahshahr, Iran).

When exposed to hot temperatures, human body dissipates heat by sweating and increasing heart rate in order to increase blood flow to the body surface, which in turn reduces the oxygen supply to muscles and brain. In addition, dehydration increases blood viscosity and makes it harder for the heart to circulate it. The physiological processes caused by increased core body temperature result in mental and physical fatigue, and augments the likelihood of exhaustion, heart attack, and mortality (Loughnan et al. 2010; Kjellstrom et al. 2016).

Dry-bulb temperature (simply referred to as temperature) is different from the temperature that the body feels. Humidity, radiation, and wind speed are among the factors influencing the real-feel temperature that human body experiences. Therefore, wet-bulb temperature (TW) has been proposed as a proxy of the real-feel temperature, and it has been utilized as a measure for human discomfort (Dunne et al. 2013). TW is more confined compared to the dry-bulb temperature and thus, it is more reliable and more accurate for assessing human health-related issues (Zhao et al. 2016).

Few studies have investigated the mortality caused by extreme temperatures. Some of them solely focused on the relationship (mostly linear correlation) between global warming and the changes in mortality (Huber et al. 2017; Mazdiyasni et al. 2017). It has been discussed that climate change is not the only cause for mortality. In fact, heat-related excessive mortality may occur at any time and any location (Loughnan et al. 2010; WHO 2014). Therefore, health risk models have been developed in recent years to quantify the

heat-related mortality risk, and a robust scientific research question is to assess how climate change aggravates mortality risk (Honda et al. 2014).

This chapter investigates the impacts of climate change and global warming on the mortality risk caused by extreme high temperatures. An ensemble of regional climate models (RCMs) are implemented to calculate TW across the MENA. The mortality risk is then quantified using a recently developed health risk model, and the impacts of climate change on the mortality risk caused by excessive heat stress is investigated.

5.2 Data

MENA is located between the latitudes 6.6°S–42°N and longitudes 20°W–60°E covering parts of 70 countries and accommodating over 600 million inhabitants. The climate of the region is mostly characterized by hot arid areas with very low precipitation.

Daily maximum near surface temperature (T_x) and relative humidity (hurs) are acquired during summer (June, July, and August) for 17 RCMs, observation, and reanalysis datasets. For climate data, we utilized RCMs developed by Coordinated Regional Climate Downscaling Experiment (CORDEX) (Jones et al. 2011). The CORDEX RCMs are developed at 14 different domains across the world, two of which cover the MENA region and their spatial overlap is used in this study. T_x and hurs are acquired from 17 RCMs at a daily temporal resolution and 0.44° spatial resolution for summers during the historical period of 1951-2005 and two future scenarios of RCP4.5 (corresponding to 2°C global warming by the end of 21st century) and RCP8.5 (business as usual scenario) for the period

of 2006-2100. More information about the RCMs used in this study are provided in **Table 5-1**.

Table 5-1. The 17 RCMs used in this study and their characteristics. All the RCMs have a spatial resolution of 0.44°.

For observation, CRU (Climate Research Unit) dataset is utilized for the period of 1951-2016 at a monthly timescale and 0.5° spatial resolution (Harris et al. 2014). Moreover, daily data from ERA-interim reanalysis are also acquired for the period of 1979-2015 at 0.4° spatial resolution (Dee et al. 2011). To ensure spatial consistency, the observed

and reanalysis data are interpolated to 0.44° spatial resolution using a bilinear interpolation technique.

5.3 Methodology

5.3.1 Calculating Wet-bulb Temperature (TW)

The first step of the analysis is to calculate daily TW. To do so, an empirical equation developed by Stull (2011) is used, which is based on air temperature and relative humidity, as follows:

$$T_w = T \operatorname{atan} \left[0.151977(RH\% + 8.313659)^{\frac{1}{2}} \right] + \operatorname{atan}(T + RH\%) - \operatorname{atan}(RH\% - 1.676331) + 0.00391838(RH\%)^{\frac{3}{2}} \operatorname{atan}(0.023101RH\%) - 4.686035 \quad \mathbf{5-1}$$

where T is the dry-bulb air temperature in Celsius, RH% indicates the relative humidity, and T_w is the TW in Celsius.

Daily TW is calculated using Equation **5-1** for each RCM over the period of 1951-2100. Although more simplified equations have been used for calculating TW in other studies (e.g. Mitchell 2016), the equation used here has proved to be accurate for high temperatures of up to 50°C and a wide range of relative humidity (5%-99%).

5.3.2 Quantifying Mortality Risk

Some of the previous studies considered a constant threshold (e.g. $TW > 35^{\circ}\text{C}$) to investigate the health-related risks of climate change (Pal and Eltahir 2015). However, the physiological attributes of human body and its tolerance to heat is different in different regions of the world. For instance, people living in sub-Saharan Africa have been exposed to (and are adapted to) higher temperatures than those living in Northern Canada, for example. Therefore, considering spatially variable temperature threshold is necessary for reliable assessment of mortality risk.

The methodology for quantifying the impacts of excessive heat on mortality is developed by Honda et al. (2014) and it has been employed by various agencies including the World Health Organization (WHO 2014). It is based on a comprehensive global analysis of the relationship between mortality and temperature. Honda et al. (2014) showed that heat-related excessive mortality has the lowest value in an optimum temperature (T_{opt}) and it increases afterwards. They found the 84th percentile of daily maximum temperature as the closest proxy of T_{opt} in over 90% of the cities they assessed. Thus in this study, T_{opt} is calculated for each grid of each RCM as the 84th percentile of the historical daily TW. The calculated T_{opt} from each RCM is shown in **Figure 5-1**.

Figure 5-1. Optimum wet-bulb temperature calculated for each of the RCMs using the historical data of 1951-2005.

After calculating T_{opt} , relative mortality risk (RMR) is quantified based on the temperature offset ($\Delta T = T - T_{opt}$) using Equation 5-2 as follows:

$$RMR = -2.91 \cdot 10^{-5} \Delta T^3 + 0.00153 \Delta T^2 + 0.0054 \Delta T + 1 \quad 5-2$$

where RMR is the daily relative mortality risk, and it is calculated for each day during the summer. For temperatures below T_{opt} , $RMR=1$. Therefore, for the days warmer

than T_{opt} (days with $RMR > 1$), the excessive mortality risk ($RMR - 1$) is calculated. It is then aggregated for each year to obtain the annual excessive mortality risk of the year, as follows:

$$\text{Annual Excessive Mortality Risk} = \sum_{n=1}^N (RMR_n - 1) \quad 5-3$$

where N denotes the number of days (in a particular year) that $RMR > 1$. **Figure 5-2** presents the methodology for quantifying mortality risk. The plots 1a. and 1b. indicate the results for Equations 5-2 and 5-3, respectively. The figure shows that the annual excessive mortality risk of a year is a function of temperature offset (ΔT) and frequency (number of days warmer than T_{opt}). For instance, in a particular year, if 40 days are $\sim 5^\circ\text{C}$ warmer than the optimum temperature, the annual excessive mortality risk will be about 2.5.

Figure 5-2. a) The function used for quantifying the relative mortality risk based on temperature offset (Equation 5-2). b) Annual excessive mortality risk as a function of temperature offset and frequency (Equation 5-3).

After calculating the annual excessive mortality risk, it will be compared to the historical mean excessive mortality risk to provide the rate of change for the mortality risk.

$$(Mortality\ Risk\ Ratio)_i|_{i=2006:2100} = \frac{(Annual\ Excessive\ Mortality\ Risk)_i}{Historical\ Mean\ Mortality\ Risk} \quad 5-4$$

The mortality risk ratio indicates the ratio that mortality risk will change compared to the historical period. Mortality risk ratio will be assessed at decadal timescales in order to investigate the long-term impacts of climate change. The methodology is implemented separately for each RCM and each future scenario to characterize the uncertainties.

5.4 Results and Discussion

The analysis starts with assessing RCMs' ability in simulating the historical Tx compared to observation and reanalysis. Historical mean summer Tx is calculated for the common period of 1979-2005, and the results are shown in **Figure 5-3**. RCMs show acceptable performance compared to the observation for most regions. The fine-scale spatial resolution of RCMs allows them to capture the regional climate characteristics associated with the land cover and elevation patterns fairly well. Comparing CRU and ERA-interim, disparities are found, especially across the central Africa. This is reflected more clearly in **Figure 5-4** when assessing the regional Tx simulations in historical and future periods. Although CRU and ERA-interim are highly correlated, they show about 2°C difference, with CRU being warmer in most regions except for the Middle East where ERA-interim indicates higher Tx than CRU.

Figure 5-3. Historical mean summer (JJA) maximum near-surface air temperature (Tx) for the common period of 1979-2005.

Figure 5-4. Spatial mean annual Tx for five regions across the MENA for historical and future projections. The shaded area indicates the results of 17 RCMs.

The lack of accurate and reliable long-term observational data is a critical issue across most regions of Africa, which makes the evaluation of climate models a challenge. Due to the unavailability of accurate observations, the RCMs are not bias-corrected in this study. Instead, the methodology is designed such that it compares the future projections of each model with its own historical simulations to reliably assess the impacts of climate change.

The mortality risk ratio (Equation 5-4) is quantified for each RCM and each year, and the ensemble mean of 17 RCMs is calculated for 30-year periods of near future (2010-2039), intermediate future (2040-2069), and distant future (2070-2099). The results of mortality risk ratio are plotted in **Figure 5-5**. In the figure, the results for RCP4.5 are plotted on the left column, and the right column represents RCP8.5 results. **Figure 5-5** captures the regional intensification of heat-related mortality compared to the historical period. For instance, considering the results of near future (top row), the risk of heat-related mortality over the middle east is expected to be 2-3 times higher than that of the historical period. The difference between the RCP4.5 and RCP8.5 is negligible in near future and it increases through time with large differences in distant future.

Figure 5-5. Decadal mortality risk ratio compared to the historical period. The figure represents the ensemble mean of 17 RCMs and shows the exacerbation rate of mortality compared to the historical period.

Figure 5-5 shows that even if the future global temperature increase is limited to 2°C (RCP4.5), the heat-related mortality risk in western Africa will be about 10 times higher than the historical period. However, following a business as usual scenario

(RCP8.5), the mortality risk for the same region will be about 30 times higher than the historical period.

From **Figure 5-5**, the highest mortality risk is found in the areas of western Africa below the Sahara. In general, the southern regions of MENA indicate higher mortality ratio compared to northern parts, and there seems to be a latitudinal pattern associated with the risk ratio. In order to investigate for latitudinal patterns, the mortality risk ratio of each RCM is averaged over land for each latitude, and the results are plotted in **Figure 5-6**. In the figure, the results of RCMs are plotted using the shaded area, and the line in the middle represents the ensemble mean of 17 RCMs. The boxplots at the bottom of each plot show the distribution of mortality risk ratio from all models across all latitudes, as a proxy of the mortality risk over MENA in each period. Results for RCP4.5 and RCP8.5 are plotted in blue and red, respectively.

Figure 5-6. Latitudinal mean of future mortality risk ratio over land from 17 RCMs (shaded area) and the ensemble mean (bold line) for each 30-year future period. The boxplots at the bottom of each plot indicate the results across the entire MENA region.

Figure 5-6 shows that the highest mortality risk ratio across MENA is found at 12°N (also associated with the highest uncertainty), and both future scenarios indicate similar latitudinal pattern for all the periods. Considering the boxplots, the mortality risk of MENA in near future is expected to become 2-3 times higher than the historical period, with both scenarios indicating similar results. However, in distant future, it will be 3-7 and 8-20 times higher for RCP4.5 and RCP8.5, respectively. In distant future, some of the models indicate risk ratios of up to 40 times the historical mortality risk. Furthermore, **Figure 5-6** shows that although in future the moderate scenario (RCP4.5) is not much different from the business as usual scenario (RCP8.5), the latter leads to devastating mortality risk in distant future. In fact, the highest (least probable) mortality risk ratio from RCP4.5 is lower than the median (most probable) mortality risk of the RCP8.5 scenario.

Focusing again on **Figure 5-5**, the mortality risk over water is much higher than that over land, which will be a critical issue for the regions located in the Persian Gulf (e.g. Dubai) or the Mediterranean Sea (e.g. southern Italy), both among the destinations that millions of people visit each year for leisure.

In order to better understand the spatial patterns of mortality risk ratio and to figure out why it is higher over water than land, we first investigate the future temperature changes. **Figure 5-7** represents the decadal changes of maximum air temperature (ΔT_x) and wet-bulb temperature (ΔT_W) over land (the two top rows) and water (the two bottom rows). In the figure, the brown and green histograms (the first and third rows) indicate the probability density function (PDF) of the ensemble mean of ΔT_x and ΔT_W , respectively.

Furthermore, the density-type scatterplots (the second and fourth rows) are employed to compare ΔT_x and ΔT_W of all the 17 RCMs.

Figure 5-7. The change of maximum air temperature (ΔT_x) and wet-bulb temperature (ΔT_W) across MENA over land (top) and water (bottom). The histogram plots (the first and third rows) show the distribution of the ensemble mean of 17 RCMs. The density-type scatterplots (the second and fourth rows) compare ΔT_x and ΔT_W of all RCMs, with the colorbar indicating the density.

Figure 5-7 demonstrates the difference between changing patterns over land and water. From the figure, ΔT_x and ΔT_W have a linear relationship with similar values over water (the bottom rows). However, ΔT_x is always higher than ΔT_W over land (the top two rows). In simple words, the changes of dry- and wet-bulb temperature are similar over water, whereas the former is higher than the latter over land (ΔT_x over land is higher than that over water). The decadal spatial changes of T_x and T_W are shown in **Figure 5-8** to better elaborate on the regional differences. For ΔT_x , the highest increase over land is found over the Mediterranean region; whereas for ΔT_W , central African regions below the Sahel show the highest values.

Figure 5-8. Decadal mean changes of maximum near-surface air temperature (ΔT_x) and wet-bulb temperature (ΔT_W) for 30-year future periods. The figure is generated using the results of ensemble mean of 17 RCMs.

Focusing on the ΔTW in **Figure 5-7** (the green histograms) and comparing the changes over land and water (the first and third rows), ΔTW is higher over land than water. Hence, the question still remains; why is the future mortality risk ratio higher over water than land, while ΔTW shows the opposite pattern? The answer can be explored in the second factor that affects mortality: the frequency. The percentage of days with $TW > T_{opt}$ is extracted for each RCM, and the ensemble mean of the results are plotted in **Figure 5-9**. The figure shows that during the historical period, 14-18% of summer days had $TW > T_{opt}$ over land. The same for near and distant future is about 20-50% and 30-100%, respectively. However, the percentage of days with $TW > T_{opt}$ over water in near and distant future are about 40-70% and 85-100%, respectively. The combination of ΔTW (**Figure 5-8**) and frequency (**Figure 5-9**) explain the higher mortality risk ratio of water than land (**Figure 5-5**).

Figure 5-9. The percentage of the days with $TW > T_{opt}$ during each 30-year future period. The frequency is extracted for each RCM in each period, and the figure represents the ensemble mean of 17 RCMs.

Results indicate that in distant future, almost the entire summer will have a TW higher than T_{opt} over water. The reason for such high frequency is perceived by investigating the variation (standard deviation) of air temperature, as shown in **Figure 5-10**. The figure shows that the TW has low inter-annual variation over water. Therefore,

a slight increase in mean temperature translates to a shift in the frequency of occurrences. Comparing T_{opt} , ΔTW , and the changes in the frequency (plotted in **Figure 5-1**, **Figure 5-7**, and **Figure 5-10**, respectively), it is found that in general, the southwestern parts of MENA have the highest T_{opt} and indicate the highest ΔTW , eventually resulting in the highest mortality risk ratio.

Figure 5-10. (Top) standard deviation of TW during the historical period, indicating the inter-annual variations of TW. (Bottom) the changes of inter-annual standard deviation of TW in each 30-year period compared to the historical period. Standard deviation is calculated for each RCM in each period, and the figure shows the results from ensemble mean of 17 RCMs.

This study quantified the heat-related mortality risk and investigated the impacts of climate change on human mortality. It should be noted that although spatially variable T_{opt} was used, no adaptation scenario (i.e. temporally variable T_{opt}) were considered here. This is due to two main reasons: a) some studies have argued that although human body may adapt to dry-bulb temperature to some extent, its adaptation capacity is less for TW (Pal and Eltahir 2016), b) an accurate and realistic adaptation scenario should be defined based on physiological characteristics of human body as well as biological factors. It (at least) requires investigating the likely adaptation scenarios of human body during the past decades, which is beyond the scope of the current study. Albeit some studies have proposed theoretical adaptation scenarios (e.g. WHO 2014), they fail to provide a realistic and physically-based assessment. Therefore, researchers are encouraged to assess the regional characteristics of air temperature as well as social and physiological attributes of human body to develop adaptation scenarios for further heat-related assessments.

In the present study, daily maximum air temperature (i.e. the finest temporal resolution available from the CORDEX RCMs over Africa) were analyzed. Hence, it does not reflect the peak heat stress amplified by diurnal temperature cycles. Furthermore, the analysis applies to fully shaded conditions, and the effects of solar insolation and wind are neglected. Thus, for instance, the mortality risk for construction workers who work during the peak sunshine hours in a humid region is expected to be higher than that calculated here.

Numerous studies have assessed the hydrological, environmental, or economic impacts of climate change (Dai 2012; Ahmadalipour et al. 2016, 2017b). However, climate

change impacts on human and livestock have not been investigated thoroughly. This study is the first attempt of using fine-resolution CORDEX RCMs to project the health impacts of a warming world. It was shown that climate change will intensify extreme temperatures and heatwaves, which will in turn exacerbate the mortality risk across MENA. The findings of the current study are in consensus with previous studies and corroborate the need for urgent restriction and mitigation of climate change in order to attenuate future social and human-related impacts (WHO 2014; Lelieveld et al. 2016; Pal and Eltahir 2016).

5.5 Summary and Conclusion

In this section, the daily maximum near-surface air temperature and humidity from 17 RCMs are utilized to quantify the impacts of climate change on mortality risk caused by excessive heat stress. The analysis is applied to the historical period of 1951-2005 and two future scenarios of RCP4.5 and RCP8.5 for the period of 2006-2100. The main findings are summarized as follows:

- The fine-resolution CORDEX RCMs accurately capture regional land cover and elevation effects on mortality risk.
- ΔT_x and ΔT_W (changes of dry- and wet-bulb temperature) show linear relationship over water. Whereas over land, ΔT_x is always higher than ΔT_W .
- Although ΔT_W over land is higher than that of water, the mortality risk ratio over water is expected to be higher than land, due to the following reasons:

- Frequency: Surface air temperature has low variations over water, and a slight increase in mean temperature substantially increases the frequency of heatwaves over water.
- Intensity: Due to abundant humidity over water (no humidity constraint), a slight increase in surface temperature translates to wet bulb temperature increase.
- The coastal regions of the Red sea, Persian Gulf, and the Mediterranean Sea indicate the highest increase of mortality risk, respectively.
- The mortality risk ratio shows a similar latitudinal pattern over time, and the 12°N latitude indicates the highest increase of mortality among others, with the highest uncertainty.

6 Conclusions and Future Studies

In this dissertation, rigorous frameworks were developed and implemented to quantify drought risk and mortality risk. The study provided a multi-disciplinary assessment of the hydro-climatology and socio-economy of the African continent for the period of 1950-2100. The results identified substantial impacts of climate change and population growth on drought risk, and highlighted the necessity for urgent mitigation/adaptation planning and management. In general, drought hazard will be aggravated across Africa due to anthropogenic climate change, tripling the drought extent across the continent in distant future. The intensity of drought hazard is expected to increase in southern and northern parts of the continent. The total African continent population is also expected to increase from about one billion people in the early 21st century to 3-6 billion people at the end of the century.

The compounding effects of climate change, population growth, and socio-economic vulnerability changes will significantly increase drought risk. In near future, drought risk is expected to become 2-6 times higher than that of the historical period, with different scenarios indicating similar ranges. However, the risk ratio in distant future is expected to become 3-40 times higher than the historical period, and large uncertainty is found among the results of different scenarios. In general, the central African countries have limited access to natural and financial resources and they are not socially developed in many countries. Thus, the central African countries show higher drought risk ratios than other regions.

In addition, climate change will escalate the mortality risk caused by extreme temperatures over the North Africa. The results showed that in near future, mortality risk caused by heat stress will become 2-4 times higher than that in the historical period. The mortality risk in distant future is expected to become 3-7 times higher, if net emissions are limited, and 8-20 times higher, if no climate change mitigation policy is adopted. Therefore, climate change mitigation is necessary to reduce the risks of drought and heat-related mortality.

While comprehensive analyses were carried out to provide accurate and reliable assessments, this study can be further improved from various perspectives considering vulnerability, hazard, and mortality risk. Suggestions regarding improvements on each sector are introduced in the following:

a. Vulnerability

Assessing drought vulnerability depends on the chosen factors and the quality of data. Since there is no unified framework for quantifying vulnerability, this part is more subjective than the other topics. Although this study provided the most comprehensive number of factors compared to other assessments, it can still be further improved by collecting or reconstructing more socio-economic data from diverse sources at longer periods, which is a challenge, especially for Africa. A solution for the recent decades is to develop socio-economic data from remote sensing observations (Jensen and Cowen 1999; Herold et al. 2003).

b. Hazard

In this dissertation, 10 CORDEX regional climate models were utilized to assess drought hazard using the Standardized Precipitation Evapotranspiration Index (SPEI). The drought index was calculated at 12-month timescale to better reflect the long-term impacts caused by climate change (Ahmadalipour et al. 2017a). The drought hazard analyses can be further expanded using larger ensemble of climate models. Furthermore, different drought indices can be employed for characterizing drought hazard at various timescales. In general, the impacts of climate change on drought projections of the African continent has received less attention compared to other regions of the globe. The next generation of climate models, i.e. CMIP6 (Eyring et al. 2016), are expected to become available soon and that provides the opportunity to perform investigations in that regard.

c. Mortality Risk

As it has been mentioned in chapter 4, the formulation of mortality risk in this study is based on the wet-bulb temperature which has been calculated using air temperature and humidity. It can be further improved by employing more advanced formulations which consider other variables, e.g. wind speed, sunshine duration. Moreover, the assessment was implemented at daily timescale, which does not necessarily reflect peak heat-stress, and it can be further investigated by utilizing sub-daily datasets.

The drought and mortality risk assessments of this study can be implemented for other regions (e.g. sub-national levels at the United States) and explore the associated risks for different parts of the world too.
