ABSTRACT

In this dissertation we present the RICE optimizing compiler for the functional logic language Curry. This is the first general optimizing compiler for a functional logic language. Our work is based on the idea of compiling through program transformations, which we have adapted from the functional language compiler community. We also present the GAS system for generating new program transformations, which uses the power of functional logic programming to provide a flexible framework for describing transformations. This allows us to describe and implement a wide range of optimizations including inlining, shortcut deforestation, unboxing, and case shortcutting, a new optimization we developed specifically for functional logic language. We show the correctness of these optimizations and demonstrate their effectiveness. In particular, we show that RICE outperforms previous compilers by 2 or 3 orders of magnitude on standard benchmarks.

CHAPTER 1
INTRODUCTION

With all of the chaos in the world today, sometimes it is nice to just relax and make a nice Curry. But people today are impatient. They cannot wait; they want their Curry fast. This is a problem, because Curry implementations have historically been considered slow. Some have considered it unusably slow, which is a shame, because Curry is actually a great language, and can solve many problems well. In this dissertation we aim to rectify the problem of Curry taking too long. We present the RICE Curry compiler, and show how it can deliver a fast, satisfying, Curry.

1.1 WHY CURRY?

Functional logic programming is a very powerful technique for expressing complicated ideas in a simple form. Curry implements these ideas with a clean, easy to read syntax, which is similar to Haskell, a well known functional programming language. It is also lazy, so evaluation of Curry programs is similar to Haskell as well. Curry extends Haskell with two concepts from logic programming. First, there are non-deterministic functions, such as “?”. Semantically $\mathit{a} \ ? \mathit{b}$ will evaluate $\mathit{a}$ and $\mathit{b}$ and will return both answers to the user. Second, there are free, or logic, variables. A free variable is a variable that is not in the scope of the current function. The value of a free variable is not defined, but it may be constrained.

These features are very useful for solving constraint problems. Consider the
problem of scheduling a test for a large class of students. Since the class is so large, the students cannot take the test at the same time. To solve this problem we allow each student to choose all times that they are available to take the test. After they have selected their times we partition the students into groups, where each group corresponds to a testing time, and each group is less than a given capacity.

This is a solvable problem in any language, but the solution in Curry is both concise and easily understood.

\[
\text{data } Time = \text{Int} \\
\text{data } Name = \text{String} \\
\text{data } Student = (\text{Name}, [\text{Time}]) \\
\text{data } Test = [\text{Name}] \\
\]

\[
\text{Schedule } :: [\text{Test}] \rightarrow [\text{Student}] \rightarrow [\text{Test}] \\
\text{Schedule tests } = \text{foldr takeTest tests} \\
\text{takeTest } :: \text{Student } \rightarrow [\text{Test}] \rightarrow [\text{Test}] \\
\text{takeTest } (\text{name}, \text{times}) \text{ tests } = \text{anyOf (map (testAt name tests) times)} \\
\text{testAt } :: \text{Name } \rightarrow [\text{Test}] \rightarrow \text{Time } \rightarrow [\text{Test}] \\
\text{testAt } \text{name tests} \text{k} \\
\quad | \text{length tests } < \text{capacity} \\
\quad = \text{ts1 } + [\text{name : test} ] + \text{ts2} \\
\text{where } (\text{ts1}, \text{test : ts2}) = \text{splitAt k}
\]

The students are scheduled one at a time. Each student has a name, and a list of times that they are available to test. We non-deterministically place the student in one of the times they marked as available. To place a student in the \(k^{th}\) test, we split the list into the tests before \(k\), which we call \(ts1\), and the lists after \(k\), which we call \(ts2\). Finally, we check that after putting the student in test \(k\), That test will still be below the capacity.

We give a fuller account of the semantics in chapters 1.5 and 2.7.
1.2 CURRENT COMPILERS

There are currently two mature Curry compilers, Pakcs \[38\] and Kics2 \[28\]. Pakcs compiles Curry to Prolog in an effort to leverage Prolog’s non-determinism and free variables. Kics2 compiles Curry to Haskell in an effort to leverage Haskell’s higher-order functions and optimizing compiler. Both compilers have their advantages. Pakcs tends to perform better on non-deterministic expressions with free variables, where Kics2 tends to perform much better on deterministic expressions. Unfortunately neither of these compilers perform well in both circumstances.

Sprite \[19\], an experimental compiler, aims to fix these inefficiencies. The strategy is to compile to a virtual assembly language, known as LLVM. So far, Sprite has shown promising improvements over both Pakcs and Kics2 in performance, but it is not readily available for testing at the time of this writing.

Similarly Mcc \[78\] also worked to improve performance by compiling to C. While Mcc often ran faster than both Pakcs or Kics2, it could perform very slowly on common Curry examples. It is also no longer in active development.

One major disadvantage of all four compilers is that they all attempt to pass off optimization to another compiler. Pakcs attempts to have Prolog optimize the non-deterministic code; Kics2 attempts to use Haskell to optimize deterministic code; Sprite attempts to use LLVM to optimize the low level code; and Mcc simply did not optimize its code. Unfortunately none of these approaches works very well. While some implementations of Prolog can optimize non-deterministic expressions, they have no concept of higher-order functions, so there are many optimizations that cannot be applied. Kics2 is in a similar situation. In order to incorporate non-deterministic computations in Haskell, a significant amount of code must be threaded through each computation. This means that any non-deterministic expression cannot be optimized in Kics2. Finally, since LLVM does not know about either higher-order functions or non-determinism, it loses many easy opportunities
for optimization.

Curry programs have one last hope for efficient execution. Recently, many scientists \cite{87, 88} have developed a strong theory of partial evaluation for functional logic programs. While these results are interesting, partial evaluation is not currently automatic in Curry. Guidance is required from the programmer to run the optimization. Furthermore, the optimization fails to optimize several common programs.

1.3 THE NEED FOR OPTIMIZATIONS

So far, none of these approaches have included the large body of work on program optimizations \cite{1, 2, 4-6, 21, 22, 41, 43, 46, 60, 64, 68, 77, 96, 100, 101}. This leads to the inescapable conclusion that Curry needs an optimizer. We propose a new compiler environment for developing and testing optimizations, which we call the Reduction Inspired Compiler Environment (\texttt{RICE}) Curry compiler. This compiler is intended to make developing new optimizations for Curry as simple as possible. We test this idea by developing several common optimizations for the \texttt{RICE} compiler. Furthermore we implement three specific optimizations for Curry, Unboxing \cite{91}, Case Shortcutting \cite{18}, and Deforestation \cite{46}. While Unboxing and Deforestation are well known in the function languages community, the techniques have not been applied in a function logic setting. Case Shortcutting is a unique optimization for functional logic programs. We chose these optimizations specifically because they focus on reducing the amount of memory consumed by programs, which is a common problem for Curry programs \cite{75}.

1.4 CONTRIBUTIONS

This work focuses on the construction of an efficient compiler for the Curry programming language. The main contributions of this dissertation are as follows.
• We build an efficient implementation of the Curry language. (Section 3.2.2)

• We identify aspects of existing Curry compilers, Kics2 and Pakcs, that lead to inefficiency. Specifically:

  – We show that compilation of Curry does not require converting all programs to Uniform Programs [26], which is more efficient than Kics2’s compilation scheme. (Section 3.2.3)

  – We give a new backtracking algorithm that omits backtracking deterministic expressions, which is more efficient than backtracking in Pakcs. (Section 3.2.6)

• We state and prove the Path Compression Theorem, which justifies several of our transformations, as well as improvements to the run-time system. (Section 3.2.6)

• We introduce the GAS system, which is a library for constructing program transformations. This is not a new idea [61], but we show how using functional logic ideas can improve the implementation. (Section 5.1.1)

• We show that, after converting programs to A-Normal Form, important optimizations that are valid for lazy functional programs are also valid for lazy functional logic programs. Specifically, we show that both inlining and reduction remain valid for Curry programs, which is not true without the conversion to A-normal form. (Section 7.1)

• We implement three memory optimizations that have not been previously implemented for functional logic programs. (Chapter 7.3.5)

  – We implement unboxing by making boxes first class values in our language [91], and justify its correctness. (Section 8.1)
We show a new optimization for functional logic programs called case shortcutting. We show the problems with trying to elide constructing a node that is evaluated in a case expression, then we show how this problem can be solved with a new node. (Section 8.2)

We implement shortcut deforestation [46], and show that, under suitable conditions, it remains correct for functional logic programs. In order to get decent performance out of this optimization, we develop a scheme for outlining and optimizing partial applications. (Section 8.3)

- We show that programs compiled with RICE are anywhere from 10 to 1000 times faster than those compiled with the Kics2 compiler, which is the current state of the art. (Section 9.1)

- We show that programs compiled with optimizations are almost always at least twice as fast as those compiled without, and sometimes up to twenty times as fast. (Section 9.1)

1.5 OVERVIEW

The rest of this dissertation is organized as follows. Chapter 1.5 presents the mathematical background of Term and Graph Rewriting. Notions from rewriting will be used throughout this dissertation, both because the operational semantics of Curry were first described using rewriting, and because our optimizing engine is based on constructing rewrite rules. Chapter 2.7 presents the Curry Language and its semantics. We introduce the Curry language and describe the IR FlatCurry as well as some conceptual hurdles with implementing a functional logic language. We also introduce two novel approaches to improving the performance of evaluation, case function and fast backtracking. Case functions can be applied to any evaluation model for Curry, while fast backtracking is specific to backtracking
implementations. Chapter 3.2.7 discusses the target code for this compiler. We describe, by example, the generated code for simple functions, then we describe the changed needed to add additional features of Curry. Chapter 4.3 introduces the GAS system for implementing optimizations. This is arguably the most important contribution to this paper, as it showcases how Curry can improve the process of writing large pieces of software like optimizing compilers. We describe the system, its implementation, and show how to construct optimizations with it. Chapter 5.1.5 overviews the compiler pipeline, and the translation to C. We show the compiler pipeline, and how GAS simplifies several of the transformations. Chapter 6.3 discusses the implementation of several common optimizations. We show several common optimizations including inlining, reduction, and case canceling. We also introduce A-Normal form, which is required for the correctness of these optimizations. Chapter 7.3.5 discusses the implementation of Unboxing, Shortcutting, and Deforestation. Chapter 8.3.5 shows the results of our optimizations. Finally, Chapter 9.1 concludes and discusses future work.
When cooking, it is very important to follow the rules. You do not need to stick
to an exact recipe, but you do need to know the how ingredients will react to
temperature and how different combinations will taste. Otherwise you might get
some unexpected reactions.

Similarly, there is not a single way to compile Curry programs, however we
do need to know the rules of the game. Throughout this compiler, we will be
transforming Curry programs in many different ways, and it is important to make
sure that all of these transformations respect the rules of Curry. As we will see, if
we break these rules, then we may get some unexpected results.

We review the theory of term Rewriting following the style of Ohlebusch [85],
along with the more specific Term and Graph Rewriting. We give a basic intuition
about how to apply these topics, and show several examples using a small, but not
trivial, example of a rewrite system for Peano Arithmetic [2.9]. We will use these
concepts to define the semantics of Curry, as well as develop optimizations.

2.1 REWRITING

In programming language terms, the rules of Curry are its semantics. The seman-
tics of Curry are generally given in terms of rewriting. [11, 14, 50] While there are
other semantics [3, 49, 97], rewriting is a common formalism for many functional
languages, and the general theory of Curry grew out of this discipline [11], a good
fit for Curry [37]. We will give a definition of rewrite systems, then we will look at
two distinct types of rewrite systems: Term Rewrite Systems, which are used to implement transformations and optimizations on the Curry syntax trees; and Graph Rewrite Systems, which define the operational semantics for Curry programs. This mathematical foundation will help us justify the correctness of our transformations even in the presence of laziness, non-determinism, and free variables.

An Abstract Rewriting System (ARS) is a set $A$ along with a relation $\rightarrow$. We use $a \rightarrow b$ as a shorthand for $(a, b) \in \rightarrow$, and we have several modifiers on our relation.

- $a \rightarrow^n b$ iff $a = x_0 \rightarrow x_1 \rightarrow \ldots x_n = b$.
- $a \rightarrow^{\leq n} b$ iff $a \rightarrow^i b$ and $i \leq n$.
- Reflexive closure: $a \rightarrow^= b$ iff $a = b$ or $a \rightarrow b$.
- Symmetric closure: $a \leftrightarrow b$ iff $a \rightarrow b$ or $b \rightarrow a$.
- Transitive closure: $a \rightarrow^+ b$ iff $\exists n \in \mathbb{N}. a \rightarrow^\leq n b$.
- Reflexive transitive closure: $a \rightarrow^* b$ iff $a \rightarrow^= b$ or $a \rightarrow^+ b$.
- Rewrite derivation: a sequence of rewrite steps $a_0 \rightarrow a_1 \rightarrow \ldots a_n$.
- $a$ is in Normal Form (NF) if no rewrite rules can apply.

A rewrite system is meant to invoke the feeling of algebra. In fact, rewrite systems are much more general, but they can still retain the feeling. If we have an expression $(x \cdot x + 1)(2 + x)$, we might reduce this with the reduction in Figure 2.1.

We can conclude that $(x \cdot x + 1)(x + 2) \rightarrow^+ x^3 + 2x^2 + x + 2$. This idea of rewriting invokes the feel of algebraic rules. The mechanical process of rewriting allows for a simple implementation on a computer.

It is worth understanding the properties and limitations of these rewrite systems. Traditionally there are two important questions to answer about any rewrite system. Is it confluent? Is it terminating?
\[(x \cdot x + 1)(2 + x)\]
\[\rightarrow (x \cdot x + 1)(x + 2)\] by commutativity of addition
\[\rightarrow (x^2 + 1)(x + 2)\] by definition of \(x^2\)
\[\rightarrow x^2 \cdot x + 2 \cdot x^2 + 1 \cdot x + 1 \cdot 2\] by FOIL
\[\rightarrow x^2 \cdot x + 2x^2 + x + 2\] by identity of multiplication
\[\rightarrow x^3 + 2x^2 + x + 2\] by definition of \(x^3\)

Figure 2.1: reducing \((x \cdot x + 1)(2 + x)\) using the standard rules of algebra

A *confluent* system is a system where the order of the rewrites does not change the final result. For example, consider the distributive rule. When evaluating \(3 \cdot (4 + 5)\) we could either evaluate the addition or multiplication first. Both of these reductions arrived at the same answer as can be seen in Figure 2.2.

\[
\begin{array}{c}
3 \cdot (4 + 5) \\
\rightarrow 3 \cdot 4 + 3 \cdot 5 \\
\rightarrow 12 + 15 \\
\rightarrow 27
\end{array}
\]

(a) distributing first

\[
\begin{array}{c}
3 \cdot (4 + 5) \\
\rightarrow 3 \cdot 9 \\
\rightarrow 27
\end{array}
\]

(b) reducing 4 + 5 first

Figure 2.2: Two possible reductions of \(3 \cdot (4 + 5)\). Since this is a confluent system, they both can rewrite to 27.

In a *terminating* system every derivation is finite. That means that eventually there are no rules that can be applied. The distributive rule is terminating, whereas the commutative rule is not terminating. See Figure 2.3.

Confluence and termination are important topics in rewriting, but we will
largely ignore them. After all, Curry programs are neither confluent nor terminating. However, there will be a few cases where these concepts will be important. For example, if our optimizer is not terminating, then we will never actually compile a program.

Now that we have a general notation for rewriting, we can introduce two important rewriting frameworks: term rewriting and graph rewriting, where we are transforming trees and graphs respectively.

2.2 TERM REWRITING

As mentioned previously, one application of term rewriting is to transform terms representing syntax trees. This will be useful in optimizing the Abstract Syntax Trees (ASTs) of Curry programs. Term rewriting is a special case of abstract rewriting. Therefore everything from abstract rewriting will apply to term rewriting.

A term is made up of signatures and variables. \[ \text{Def 3.1.2} \] We let $\Sigma$ and $V$ be two arbitrary alphabets, but we require that $V$ be countably infinite, and $\Sigma \cap V = \emptyset$ to avoid name conflicts. A signature $f^{(n)}$ consists of a name $f \in \Sigma$ and an arity $n \in \mathbb{N}$. A variable $v \in V$ is just a name. Finally a term is defined inductively. The term $t$ is either a variable $v$, or it is a signature $f^{(n)}$ with children $t_1, t_2, \ldots, t_n$, where
$t_1, t_2, \ldots, t_n$ are all terms. We write the set of terms all as $T(\Sigma, V)$. If $t \in T(\Sigma, V)$ then we write $\text{Var}(t)$ to denote the set of variables in $t$. By definition $\text{Var}(t) \subseteq V$. We say that a term is \textit{linear} if no variable appears twice in the term [Def. 3.2.4].

This inductive definition gives us a tree structure for terms. As an example consider Peano arithmetic $\Sigma = \{+, -, 0^0, S^1, \text{True}^0, \text{False}^0\}$. We can define the term $\ast(+(0, S(0)), +(S(0), 0))$. This gives us the tree in Figure 2.4. Every term can be converted into a tree like this and vice versa. The symbol at the top of the tree is called the root of the term.

![Figure 2.4: Tree representation of the term $\ast(+(0, S(0)), +(S(0), 0))$.](image)

A \textit{child} $c$ of term $f(t_1, t_2, \ldots, t_n)$ is one of $t_1, t_2, \ldots, t_n$. A \textit{subterm} $s$ of $t$ is either $t$ itself, or it is a subterm of a child of $t$. We write $s = t|_p$ where $p = [i_1, i_2, \ldots, i_n]$ to denote that $t$ has child $t_{i_1}$ which has child $t_{i_2}$ and so on until $t_{i_n} = s$. Note that we can define this recursively as $t|[i_1,i_2,\ldots,i_n] = t_{i_1}|[i_2,\ldots,i_n]$, which matches our definition for subterm. We call $[i_1, i_2, \ldots, i_n]$ the \textit{path} from $t$ to $s$ [Def 3.1.5]. We write $\epsilon$ for the empty path, and $i:p$ for the path starting with the number $i$ and followed by the path $p$, and $p \cdot q$ for concatenation of paths $p$ and $q$.

In our previous term $S(0)$ is a subterm in two different places. One occurrence is at path $[0, 1]$, and the other is at path $[1, 0]$. 
We write $t[r \leftarrow p]$ to denote replacing subterm $t|_p$ with $r$. We define the algorithm for this in Figure 2.5.

$t[r \leftarrow \epsilon] = r$

$f(t_1, \ldots t_i, \ldots t_n)[r \leftarrow i:p] = f(t_1, \ldots t_i[r \leftarrow p], \ldots t_n)$

Figure 2.5: algorithm for finding a subterm of $t$.

In our above example $t = \ast((0, S(0)), (S(0), 0)))$, We can compute the rewrite $t[(S(0), S(0)) \leftarrow [0, 1]]$, and we get the term $\ast((0, \ast(S(0), S(0))), (S(0), 0))$, with the tree in Figure 2.6.

A substitution replaces variables with terms. Formally, a substitution is a mapping from $\sigma: V \rightarrow T(\Sigma, V)$, such that $\sigma(x) \neq x$ [Def. 3.1.7]. We write $\sigma = \{v_1 \mapsto t_1, \ldots v_n \mapsto t_n\}$ to denote the substitution where $s(v_i) = t_i$ for $i \in \{1 \ldots n\}$, and $s(v) = v$ otherwise. We can uniquely extend $\sigma$ to a function on terms by Figure 2.7.
\[ \sigma'(v) = \sigma(v) \]
\[ \sigma'(f(t_1, \ldots t_n)) = f(\sigma'(t_1) \ldots \sigma'(t_n)) \]

Figure 2.7: Algorithm for applying a substitution.

Since this extension is unique, we will just write \( \sigma \) instead of \( \sigma' \). Term \( t_1 \) matches term \( t_2 \) if there exists some substitution \( \sigma \) such that \( t_1 = \sigma(t_2) \) [3.1.8]. We call \( \sigma \) a matcher. Two terms \( t_1 \) and \( t_2 \) unify if there exists some substitution \( \sigma \) such that \( \sigma(t_1) = \sigma(t_2) \) [3.1.8]. In this case \( \sigma \) is called a unifier for \( t_1 \) and \( t_2 \).

We can order substitutions based on what variables they define. A substitution \( \sigma \leq \tau \), iff, there is some substitution \( \nu \) such that \( \tau = \nu \circ \sigma \). The relation \( \sigma \leq \tau \) should be read as \( \sigma \) is more general than \( \tau \), and it is a quasi-order on the set of substitutions. A unifier \( u \) for two terms is most general (or an mgu), iff, for all unifiers \( v \), \( v \leq u \). Mgu’s are unique up to renaming of variables. That is, if \( u_1 \) and \( u_2 \) are mgu’s for two terms, then \( u_1 = \sigma_1 \circ u_2 \) and \( u_2 = \sigma_2 \circ u_1 \). This can only happen if \( \sigma_1 \) and \( \sigma_2 \) just rename the variables in their terms.

As an example \( +(x, y) \) matches \( +(0, S(0)) \) with \( \sigma = \{ x \mapsto 0, y \mapsto S(0) \} \). The term \( +(x, S(0)) \) unifies with term \( +(0, y) \) with unifier \( \sigma = \{ x \mapsto 0, y \mapsto S(0) \} \). If \( \tau = \{ x \mapsto 0, y \mapsto S(z) \} \), then \( \tau \leq \sigma \). We can define \( \nu = \{ z \mapsto 0 \} \), and \( \{ \sigma = \nu \circ \tau \} \)

Now that we have a definition for a term, we need to be able to rewrite it. A rewrite rule \( l \rightarrow r \) is a pair of terms. However this time we require that \( \text{Var}(r) \subseteq \text{Var}(l) \), and that \( l \not\in V \). A Term Rewriting System (TRS) is the pair \((T(\Sigma, V), R)\) where \( R \) is a set of rewrite rules.

Definition 2.2.1. Rewriting: Given terms \( t, s \), path \( p \), and rule \( l \rightarrow r \), we say that \( t \) rewrites to \( s \) if, \( l \) matches \( t|_p \) with matcher \( \sigma \), and \( t[\sigma(r) \leftarrow p] = s \). The term \( \sigma(l) \) is the redex, and the term \( \sigma(r) \) is the contractum of the rewrite.

There are a few important properties of rewrite rules \( l \rightarrow r \). A rule is left or
right linear if \( l \) or \( r \) is linear respectively \[85]\text{Def. 3.2.4}. A rule is *collapsing* if \( r \in V \). A rule is *duplicating* if there is an \( x \in V \) that occurs more often in \( r \) than in \( l \) \[85]\text{Def. 3.2.5}.

Two terms \( s \) and \( t \) are *overlapping* if \( t \) unifies with a subterm of \( s \), or \( s \) unifies with a subterm of \( t \) at a non-variable position \[85]\text{Def. 4.3.3}. Two rules \( l_1 \rightarrow r_1 \) and \( l_2 \rightarrow r_2 \) if \( l_1 \) and \( l_2 \) overlap. A rewrite system is *overlapping* if, and only if, any two rules overlap. Otherwise it is non-overlapping. Any non-overlapping left linear system is *orthogonal* \[85]\text{Def. 4.3.4}. Orthogonal systems have several nice properties, such as the following theorem \[85]\text{Thm. 4.3.11}.

**Theorem 1.** Every orthogonal TRS is confluent.

As an example, in Figure 2.8 examples (b) and (c) both overlap. It is clear that these systems are not confluent, but non-confluence can arise in more subtle ways. The converse to theorem 2.1 is not true. There can be overlapping systems which are confluent.

![Three TRSs demonstrating how rules can overlap.

(a) A non-overlapping system

(b) A system that overlaps at the root

(c) A system that overlaps at a subterm](image)

Figure 2.8: Three TRSs demonstrating how rules can overlap. In (a) they do not overlap at all, In (b) both rules overlap at the root, and in (c) rule 2 overlaps with a subterm of rule 1.

When defining rewrite systems we usually follow the constructor discipline; we separate the set \( \Sigma = C \cup F \). \( C \) is the set of *constructors*, and \( F \) is the set of *function symbols*. Furthermore, for every rule \( l \rightarrow r \), the root of \( l \) is a function
symbol, and every other symbol is a constructor or variable. We call such systems constructor systems. As an example, the rewrite system for Peano arithmetic is a constructor system.

</table>

Figure 2.9: The rewrite rules for Peano Arithmetic with addition, multiplication, subtraction, and comparison. All operators use infix notation.

The two sets are \( C = \{0, S, True, False\} \) and \( F = \{+, *, -, \leq\} \), and the root of the left hand side of each rule is a function symbol. In contrast, the SKI system is not a constructor system. While \( S, K, I \) can all be constructors, the \( Ap \) symbol appears in both root and non-root positions of the left hand side of rules. This example will become important for us in Curry. We will do something similar to implement higher-order functions. This means that Curry programs will not
directly follow the constructor discipline. Therefore, we must be careful when specifying the semantics of function application.

\[
\begin{align*}
Ap(I, x) & \rightarrow x \\
Ap(Ap(K, x), y) & \rightarrow x \\
Ap(Ap(Ap(S, x), y), z) & \rightarrow Ap(Ap(x, z), Ap(y, z))x
\end{align*}
\]

Figure 2.10: The SKI system from combinatorial logic.

Constructor systems have several nice properties. They are usually easy to analyze for confluence and termination. For example, if the left hand side of two rules do not unify, then they cannot overlap. We do not need to check if subterms overlap. Furthermore, any term that consists entirely of constructors and variables is in normal form. For this reason, it is not surprising that most functional languages are based on constructor systems.

2.3 NARROWING

Narrowing was originally developed to solve the problem of semantic unification. The goal was, given a set of equations \(E = \{a_1 = b_2, a_2 = b_2, \ldots a_n = b_n\}\), to solve the equation \(t_1 = t_2\) for arbitrary terms \(t_1\) and \(t_2\). Here a solution to \(t_1 = t_2\) is a substitution \(\sigma\) such that \(\sigma(t_1)\) can be transformed into \(\sigma(t_2)\) by the equations in \(E\).

As an example let \(E = \{\ast(x + (y, z)) = +((x, y), \ast(x, z))\}\) Then the equation \(\ast(1, +(x, 3)) = +(+(1, 4), \ast(y, 5), \ast(z, 3))\) is solved by \(\sigma = \{x \mapsto +45, y \mapsto 1, z \mapsto 1\}\). The derivation is in Figure 2.11.

Unsurprisingly, there is a lot of overlap with rewriting. One of the earlier solutions to this problem was to convert the equations into a confluent, terminating rewrite system. Unfortunately, this only works for ground terms, that is, terms
\[
\sigma(*((1, + (x, 3)))) = \\
*(1, +(4, 5), 3)) = \\
+(*(1, +(4, 5)), *(1, 3)) = \\
+(+(*(1, 4), *(1, 5)), *(1, 3)) = \\
\sigma(+(+(1, 4), *(y, 5)), *(z, 3)))
\]

Figure 2.11: Derivation of \( *((1, + (x, 3))) = +(+(*(1, 4), *(y, 5)), *(z, 3)) \) with \( \sigma = \{ x \mapsto +(4, 5), y \mapsto 1, z \mapsto 1 \} \).

without variables. However, this idea still has merit. So we want to extend it to terms with variables.

Before, when we rewrote a term \( t \) with rule \( l \rightarrow r \), we assumed it was a ground term, then we could find a substitution \( \sigma \) that would match a subterm \( t|_p \) with \( l \), so that \( \sigma(l) = t|_p \). To extend this idea to terms with variables in them, we look for a unifier \( \sigma \) that unifies \( t|_p \) with \( l \). This is really the only change we need to make \[85\]. However, now we record \( \sigma \), because it is part of our solution.

**Definition 2.3.1.** Narrowing: Given terms \( t, s \), path \( p \), and rule \( l \rightarrow r \), we say that \( t \) narrows to \( s \) if, \( l \) unifies with \( t|_p \) with unifier \( \sigma \), and \( t[\sigma(r) \leftarrow p] = s \). We write \( t \narrow_{p,l \rightarrow r,\sigma} s \). We may write \( t \narrow_{\sigma} s \) if \( p \) and \( l \rightarrow r \) are clear.

Notice that this is almost identical to the definition of rewriting. The only difference is that \( \sigma \) is a unifier instead of a matcher.

Narrowing was first developed to solve equations for automated theorem provers \[94\]. However, for our purposes it is more important that narrowing allows us to rewrite terms with free variables. \[51\]

At this point, rewrite systems are a nice curiosity, but they are completely impractical. This is because we do not have a plan for solving equations in them. In the definition for both rewriting and narrowing, we did not specify how to find
\( \sigma \) the correct rule to apply, or even what subterm to apply the rule.

In confluent terminating rewrite systems, we could simply try every possible rule at every possible position with every possible substitution. Since the system is confluent, we could choose the first rule that could be successfully applied, and since the system is terminating, we would be sure to find a normal form. In a narrowing system, this is still not guaranteed to halt, because there could be an infinite number of substitutions. This is the best possible case for rewrite systems, and we still cannot ensure that our algorithm will finish. We need a systematic method for deciding what rule should be applied, what subterm to apply it to, and what substitution to use. This is the role of a strategy.

### 2.4 REWRITING STRATEGIES

Our goal with a rewriting strategy is to be able to find a normal form for any term. Similarly our goal for narrowing will be to find a normal form and substitution. However, we want to be efficient when rewriting. We would like to use only local information when deciding what rule to select. We would also like to avoid unnecessary rewrites. Consider the following term from the SKI system defined in Figure 2.10:

\[
\text{Ap}(\text{Ap}(\text{Ap}(\text{K}, \text{I}), \text{Ap}(\text{S}, \text{Ap}(\text{I}, \text{I}))), \text{Ap}(\text{S}, \text{Ap}(\text{I}, \text{I}))))
\]

It would be pointless to reduce \( \text{Ap}(\text{Ap}(\text{S}, \text{Ap}(\text{I}, \text{I}))), \text{Ap}(\text{S}, \text{Ap}(\text{I}, \text{I}))) \) since \( \text{Ap}(\text{Ap}(\text{K}, \text{I}, z)) \) rewrites to \( \text{I} \) no matter what \( z \) is. In this particular case, since \( \text{Ap}(\text{Ap}(\text{S}, \text{Ap}(\text{I}, \text{I}))), \text{Ap}(\text{S}, \text{Ap}(\text{I}, \text{I}))) \) reduces to itself, we have turned a potentially non-terminating reduction to a terminating one.

A **Rewriting Strategy** \( S : T(\Sigma, V) \rightarrow \text{Pos} \times R \) is a function that takes a term, and returns a position to rewrite, and a rule to rewrite with. Furthermore we require that if \( (p, l \rightarrow r) = S(t) \), then \( t|_p \) is a redex that matches \( l \). The idea is that \( S(t) \) should give us a position to rewrite, and the rule to rewrite with.

For orthogonal rewriting systems, there are two common rewriting strategies.
that do not run in parallel. Innermost and outermost rewriting correspond to eager evaluation in functional programming. We rewrite the term that matches a rule that is the furthest down the tree. Outermost rewriting correspond roughly to lazy evaluation. We rewrite the highest possible term that matches a rewrite rule.

A strategy is \textit{normalizing} if, when a term \( t \) has a normal form, then the strategy will eventually find it. While outermost rewriting is not normalizing in general, it is for left-normal systems, which is a large subclass of orthogonal rewrite systems. This matches the intuition from programming languages. Lazy languages can perform computations that would run forever with an eager language.

While both of these strategies are well understood, we can actually make a stronger guarantee. We want to reduce only the redexes that are necessary to find a normal form. To formalize this we need to understand what can happen when we rewrite a term. Specifically for a redex \( s \) that is a subterm of \( t \), how can \( s \) change as we rewrite \( t \). If we were rewriting at position \( p \) with rule \( l \rightarrow r \), then there are 3 cases to consider.

Case 1: we are rewriting \( s \) itself. That is, \( s \) is the subterm \( t|_p \). Then \( s \) disappears entirely.

Case 2: \( s \) is either above \( t|_p \), or they are completely disjoint. In this case \( s \) does not change.

Case 3: \( s \) is a subterm of \( t|_p \). In this case \( s \) may be duplicated, or erased, moved, or left unchanged. It depends on whether the rule is duplicating, erasing, or right linear.

These cases can be seen in Figures \ref{fig:case1} and \ref{fig:case2}. We can formalize this with the notion of descendants with the following definition from \cite{85}[Def. 4.3.6].

\footnote{we avoid discussing parallel strategies, because our work is focused on sequential execution of Curry programs. That has been a lot of work done on parallel execution of Curry programs elsewhere \cite{52,53}.}
\[
\begin{align*}
S & \Rightarrow S \\
+ & \Rightarrow + \\
\downarrow & \downarrow \\
0 & 0 \\
S & S \\
0 & + \\
\downarrow & \downarrow \\
0 & 0 \\
+ & \Rightarrow 0
\end{align*}
\]

(a) rewrite \( R_1 \) at position \([0,1]\) does not affect \( t_{\mid 0} \).

(b) rewrite \( R_4 \) at position \([1]\) does not affect \( t_{\mid 0} \).

Figure 2.12: Four cases for the descendants for a term after a single rewrite. The boxed term is either left alone, duplicated, or erased, or moved. The rules are defined in Figure 2.9

**Definition 2.4.1.** Descendant: Let \( s = t_{\mid v} \), and \( A = l \rightarrow_{p,\sigma,R} r \) be a rewrite step in \( t \). The set of descendants of \( s \) is given by \( Des(s, A) \)

\[
Des(s, A) = \begin{cases} 
\emptyset & \text{if } v = u \\
\{s\} & \text{if } p \not\subseteq v \\
\{t_{\mid w-q} : r_{\mid w} = x\} & \text{if } p = u \cdot v \cdot q \text{ and } t_{\mid v} = x \text{ and } x \in V
\end{cases}
\]

This definition extends to derivation \( t \rightarrow_{A_1} t_1 \rightarrow_{A_2} t_2 \rightarrow_{A_2} \ldots \rightarrow_{A_n} t_{n+1} \).

\( Des(s, A_1, A_2 \ldots A_n) = \bigcup_{s' \in Des(s, A_1)} Des(s', A_2, \ldots A_n) \).

The first part of the definition is formalizing the notion of descendant. The second part is extending it to a rewrite derivation. The extension is straightforward. Calculate the descendants for the first rewrite, then for each descendant, calculate the descendants for the rest of the rewrites. With the idea of a descendant, we can
Figure 2.13: Four cases for the descendants for a term after a single rewrite. The boxed term is either left alone, duplicated, or erased, or moved. The rules are defined in Figure 2.9.
talk about what happens to a term in the future. This is necessary to describing
our rewriting strategy. Now we can formally define what it means for a redex to
be necessary for computing a normal form.

**Definition 2.4.2.** Needed: A redex $s$ that is a subterm of $t$ is *needed* in $t$ if, for
every derivation of $t$ to a normal form, a descendant of $s$ is the root of a rewrite.

This definition is good because it is immediately clear that, if we were going
to rewrite a term to normal form, we need to rewrite all of the needed redexes. In
fact, we can guarantee more than that with the following theorem \[67\].

**Theorem 2.** For an orthogonal TRS, any term that is not in normal form contains
a needed redex. Furthermore, a rewrite strategy that rewrites only needed redexes
is normalizing.

This is a very powerful result. We can compute normal forms by rewriting
needed redexes. This is also, in some sense, the best possible strategy. Every
needed redex needs to be rewritten. Now we just need to make sure our strategy
only rewrites needed redexes. There is only one problem with this plan. Determin-
ing if a redex is needed is undecidable in general. However, with some restrictions,
there are rewrite systems where this is possible \[70\][def. 3.3.7]².

**Definition 2.4.3.** Sequential A rewrite system is *sequential* if, given a term $t$ with
$n$ variables $v_1, v_2 \ldots v_n$, such that $t$ is in normal form, then there is an $i$ such that
for every substitution $\sigma$ from variables to redexes, $\sigma(v_i)$ is needed in $\sigma(t)$.

If we have a sequential rewrite system, then this leads to an efficient algorithm
for reducing terms to normal form. Unfortunately, sequential is also an undecidable
property. There is still hope. As we will see in the next section, with certain
restrictions we can ensure the our rewrite systems are sequential. Actually we can

\[²\text{The original definition used the notion of a context in normal form.}\]
make a stronger guarantee. The rewrite system will admit a narrowing strategy that only narrows needed redexes.

2.5 NARROWING STRATEGIES

Similar to rewriting strategies, narrowing strategies attempt to compute a normal form for a term using narrowing steps. However, a narrowing strategy must also compute a substitution for that term. There have been many narrowing strategies including basic [57], innermost [42], outermost [102], standard [39], and lazy [81]. Unfortunately, each of these strategies are too restrictive on the rewrite systems they allow.

\[(x + x) + x = 0\]

(a) This fails for eager narrowing, because evaluating \(x + x\) can produce infinitely many answers. However, this is fine for lazy narrowing. We will get \((0 + 0) + 0 = 0, \{x = 0\}\) or \(S(S(y + S(y)) + S(y)) = 0\{x = S(y)\}\), and the second one will fail.

\[x \leq y + y\]

(b) With a lazy narrowing strategy we may end up computing more than is necessary. If \(x\) is instantiated to 0, then we do not need to evaluate \(y + y\) at all.

Figure 2.14: Examples of where eager and lazy narrowing can fail using the rewrite system if Figure 2.9.

Fortunately there exists a narrowing strategy that is defined on a large class of rewrite systems, only narrows needed expressions, and is sound and complete. However this strategy requires a new construct called a definitional tree.

The idea is that since we are working with constructor rewrite systems, we can group all of the rules defined for the same function symbol together. We will
put them together in a tree structure defined below, and then we can compute a narrowing step by traversing the tree for the defined symbol.

**Definition 2.5.1.** $T$ is a *partial definitional tree* if $T$ is one of the following.  

- $T = \text{exempt}(\pi)$ where $\pi$ is a pattern.  
- $T = \text{leaf}(\pi \to r)$ where $\pi$ is a pattern, and $\pi \to r$ is a rewrite rule.  
- $T = \text{branch}(\pi, o, T_1, \ldots T_k)$, where $\pi$ is a pattern, $o$ is a path, $\pi|_o$ is a variable, $c_1, \ldots c_k$ are constructors, and $T_i$ is a pdt with pattern $\pi[c_i(X_1, \ldots X_n)]_o$ where $n$ is the arity of $c_i$, and $X_1, \ldots X_n$ are fresh variables.

Given a constructor rewrite system $R$, $T$ is a *definitional tree* for function symbol $f$ if $T$ is a partial definitional tree, and each leaf in $T$ corresponds to exactly one rule rooted by $f$. A rewrite system is *inductively sequential* if there exists a definitional tree for every function symbol.

The name “inductively sequential” is justified because there is a narrowing strategy that only reduces needed redexes for any of these systems. We show an example to clarify the definition. In Figure 2.15 we show the definitional tree for the $+$, $\leq$, and $=$ rules. The idea is that, at each branch, we decide which variable to inspect. Then we decide what child to follow based on the constructor of that branch. This gives us a simple algorithm for outermost rewriting with definitional trees. However, we need to extend this to narrowing.

In order to extend the strategy from rewriting to narrowing we need to figure out how to compute a substitution, and we need to define what it means for a narrowing step to be needed. The earliest definition involved finding a most general unifier for the substitution. This has some nice properties. There is a well known algorithm for computing mgus, which are unique up to renaming of variables. However, this turned out to be the wrong approach. Computing mgus is too restrictive. Consider the step $x \leq y + z \rightarrow^{2\epsilon, R_1, \{y \mapsto 0\}} x \leq z$. Without further substitutions $x \leq z$ is a
\[
\begin{align*}
0 + y & \rightarrow y \\
S(x) + y & \rightarrow S(x + y) \\
0 \leq y & \rightarrow True \\
S(x) \leq 0 & \rightarrow False \\
S(x) \leq S(y) & \rightarrow x < y \\
0 = 0 & \rightarrow True \\
S(x) = 0 & \rightarrow False \\
0 = S(y) & \rightarrow False \\
S(x) = S(y) & \rightarrow x = y \\
0 = 0 & \rightarrow True \\
0 = S(y) & \rightarrow False \\
S(x) = 0 & \rightarrow False \\
S(x) = S(y) & \rightarrow x = y
\end{align*}
\]
normal form, and \{y \mapsto 0\} is an mgu. Therefore this should be a needed step. But if we were to instead narrow \(x\), we have \(x \leq y + z \leadsto_{e, R_8, \{z \mapsto 0\}} \text{True}\). This step never needs to compute a substitution for \(y\). Therefore we need a definition that is not dependent on substitutions that might be computed later.

**Definition 2.5.2.** A narrowing step \(t \leadsto_{p, R, \sigma} s\) is needed, iff, for every \(\eta \geq \sigma\), there is a needed redex at \(p\) in \(\eta(t)\).

Here we do not require that \(\sigma\) be an mgu, but, for any less general substitution, it must be the case that we were rewriting a needed redex. So our example, \(x \leq y + z \leadsto_{2i, R_1, \{y \mapsto 0\}} x \leq z\), is not a needed narrowing step because \(x \leq y + z \leadsto_{2i, R_1, \{x \mapsto 0, y \mapsto 0\}} 0 \leq z\), is not a needed rewriting step.

Unfortunately, this definition raises a new problem. Since we are no longer using mgus for our unifiers, we may not have a unique step for an expression. For example, \(x < y \leadsto_{e, R_8, \{x \mapsto 0\}} \text{True}\), and \(x < y \leadsto_{e, R_9, \{x \mapsto S(u), t \mapsto S(v)\}} u \leq v\) are both possible needed narrowing steps.

Therefore we define a **Narrowing Strategy** \(S\) as a function from terms to a set of triples of a position, rule, and substitution, such that if \((p, R, \sigma) \in S(t)\), then \(\sigma(t)|_p\) is a redex for rule \(R\).

At this point we have everything we need to define a needed narrowing strategy.

**Definition 2.5.3.** Let \(t\) be a term rooted by function symbol \(f\), \(T\) be the definitional tree for \(f\), and ‘?’ be a distinguished symbol to denote that no rule could
The function $\lambda$ is a narrowing strategy. It takes an expression rooted by $f$, and the definition tree for $f$, and it returns a position, rule and substitution for a narrowing step. If we reach a rule node, then we can just rewrite; if we reach an exempt node, then there is no possible rewrite; if we reach a branch node, then we match a constructor; but if the subterm we were looking at is not a constructor, then we need to narrow that subterm first.

**Theorem 3.** $\lambda$ is a needed narrowing strategy. Furthermore, $\lambda$ is sound and complete.

It should be noted that while $\lambda$ is complete with respect to finding substitutions and selecting rewrite rules [11], this says nothing about the underlying completeness of the rewrite system we were narrowing. We may still have non-terminating derivations.

This needed narrowing strategy is important in developing the evaluation strategy for Curry programs. In fact, one of the early stages of a Curry compiler is
to construct definitional trees for each function defined. However, if we were to implement our compiler using terms, it would be needlessly inefficient. We solve this problem with graph rewriting.

2.6 GRAPH REWRITING

As mentioned above term rewriting is too inefficient to implement Curry. Consider the rule $\text{double}(x) = x + x$. Term rewriting requires this rule to make a copy of $x$, no matter how large it is, whereas we can share the variable if we use a graph. In programming languages, this distinction moves the evaluation strategy from “call by name” to “call by need”, and it is what we mean when we refer to “lazy evaluation”.

As a brief review of relevant graph theory: A graph $G = (V, E)$ is a pair of vertices $V$ and edges $E \subseteq V \times V$. We will only deal with directed graphs, so the order of the edge matters. A rooted graph is a graph with a specific vertex $r$ designated as the root. The neighborhood of $v$, written $N(v)$ is the set of vertices adjacent to $v$. That is, $N(v) = \{u \mid (v, u) \in E\}$. A path $p$ from vertex $u$ to vertex $v$ is a sequence $u = p_1, p_2 \ldots p_n = v$ where $(p_i, p_{i+1}) \in E$. A rooted graph is connected if there is a path from the root to every other vertex in the graph. A graph is strongly connected if, for each pair of vertices $(u, v)$, there is a path from $u$ to $v$ and a path from $v$ to $u$. A path $p$ is a cycle\footnote{Some authors will use walk and tour and reserve path and cycle for the cases where there are no repeated vertices. This distinction is not relevant for our work.} if its endpoints are the same. A graph is acyclic if it contains no cycles. Such graphs are referred to as Directed Acyclic Graphs, or DAGs. A graph $H$ is a subgraph of $G$, $H \subseteq G$ if, and only if, $V_H \subseteq V_G$ and $E_H \subseteq E_G$. A strongly connected component $S$ of $G$ is a subgraph that is strongly connected. We will use the well-known facts that strongly connected components partition a graph. The component graph, which is obtained by shrinking the strongly connected components to a single vertex, is
a DAG. To avoid confusion with variables, we will refer to vertices of graphs as nodes.

We define term graphs in a similar way to terms. Let $\Sigma = C \cup F$ be an alphabet of constructor and function names respectively, and $V$ be a countably infinite set of variables. A term graph is a rooted graph $G$ with nodes in $N$ where each node $n$ has a label in $\Sigma \cup V$. We will write $L(n)$ to refer to the label of a node. If $(n, s) \in E$ is an edge, then $s$ is a successor of $n$. In most applications the order of the outgoing edges does not matter, however it is very important in term graphs. So, we will refer to the first successor, second successor and so on. We denote this the same way we did with terms $n_i$ is the $i$th successor of $n$. The arity of a node is the number of successors. Finally, no two nodes can be labeled by the same variable.

While the nodes in a term graph are abstract, in reality, they connected using pointers in the implementation. It can be helpful to keep this in mind. As we define more operations on our term graphs, there exists a natural implementation using pointers.

We will often use a linear notation to represent graphs. This has two advantages. The first is that it is exact. There are many different ways to draw the same graph, but there is only one way to write it out a linear representation. The second is that this representation corresponds closely to the representation in a computer. The notation these graphs is given by the following grammar, where the set of nodes and the set of labels are disjoint.

$$\text{Graph} \rightarrow \text{Node}$$

$$\text{Node} \rightarrow n : L (\text{Node}, \ldots \text{Node})$$

We start with the root node, and for each node in the graph, If we have not encountered it yet, then we write down the node, the label, and the list of successors.
Figure 2.16: 1. $1: + (2:/(3:x, 3), 4:/(3, 3))$,  
2. $1: \text{double}(2:x) \Rightarrow 3: + (2:x, 2)$  
3. $1: + (2:4, 1)$  
4. $1: + (2:S(3:0), 4:S(2)) \Rightarrow 5: S(6: + (3:0), 4:S(2:S(3)))$
If we have seen it, then we just write down the node. If a node does not have any successors, then we will omit the parentheses entirely, and just write down the label.

A few examples are shown in Figure 2.16. Example 1 shows an expression where a single variable is shared several times. Example 2 shows how a rewrite can introduce sharing. Example 3 shows an example of an expression with a loop. These examples would require an infinitely large term, so they cannot be represented in term rewrite systems. Example 4 shows how reduction changes from terms to graphs. In a term rewrite system, if a node is in the pattern of a redex, then it can safely be discarded. However, in graph rewriting this is no longer true.

**Definition 2.6.1.** Let $p$ be a node in $G$, then the subgraph $G|_p$ is a new graph rooted by $p$. The nodes are restricted to only those reachable from $p$.

Notice that we do not define subgraphs by paths like we did with subterms. This is because there may be more than one path to the node $p$. It may be the case that $G|_p$ and $G$ have the same nodes, such as if the root of $G$ is in a loop.

**Definition 2.6.2.** A replacement of node $p$ by graph $u$ in $g$ (written $g[u ← p]$) is given by the following procedure. For each edge $(n, p) ∈ E_g$ replace it with an edge $(n, \text{root}_u)$. Add all other edges from $E_g$ and $E_u$. If $p$ is the root of $g$, then $\text{root}_u$ is now the root.

It should be noted that when implementing Curry, we do not actually change any of the pointers when doing a replacement. Traversing the graph to find all of the pointers to $p$ would be horribly inefficient. Instead we change the contents of $p$ to be the contents of $u$.

We can define matching in a similar way to terms, but we need to be more careful. When matching terms the structure of the term must to be the same. That is, both terms must have exactly the same tree. However, when matching graphs the structure can be wildly different. Consider the following graph.
Here the graph should match the rule \(\text{and}(\text{True}, \text{True}) \rightarrow \text{True}\).

But \(\text{and}(\text{True}, \text{True})\) is a term, so they no longer have the same structure. Therefore we must be more careful about what we mean by matching. We define matching inductively on the structure of the term.

**Definition 2.6.3.** A graph \(K\) matches a term \(T\) if, and only if, \(T\) is a variable, or \(T = l(T_1, T_2 \ldots T_n)\), the root of \(K\) is labeled with \(l\), and for each \(i \in \{1 \ldots n\}\), \(K_i\) matches \(T_i\).

Now, it may be the case that we have multiple successors pointing to the same node when checking if a graph matches a pattern, but this is OK. As long as the node matches each sub pattern, then the graph will match. We extend substitutions to graphs in the obvious way. A substitution \(\sigma\) maps variables to Nodes. In this definition for matching \(\sigma\) may have multiple variables map to the same node, but this does not cause a problem.

**Definition 2.6.4.** A rewrite rule is a pair \(L \rightarrow R\) where \(L\) is a term, and \(R\) is a term graph. A graph \(G\) matches the rule if there exists subgraph \(K\) where \(K\) matches \(L\) with matcher \(\sigma\). A rewrite is a triple \((K, L \rightarrow R, \sigma)\), and we apply the rewrite with \(G[\sigma(R) \leftarrow K]\).

From here we can define narrowing similarly to how we did for terms. We do not give the definitions here, because they are similar to the definitions in term rewriting. At this point we have discussed the difference between graphs and terms, and how a replacement can be done in a graph. For our purposes in this compiler, that is all that is needed, but the definition of narrowing and properties about inductively sequential GRSs can be found in Echaned and Janodet [36]. They also show that the needed narrowing strategy is still valid for graph rewriting systems.
2.7 PREVIOUS WORK

This was not meant to be an exhaustive examination of rewriting, but rather an introduction to the concepts, since they form this theoretical basis of the Curry language. Most work on term rewriting up through 1990 has been summarized by Klop [70], and Baader and Nipkow [24]. The notation and ideas in this section largely come from Ohlebusch [85], although they are very similar to the previous two summaries. The foundations of term rewriting were laid by Church, Rosser, Curry, Feys, Newman. [32, 34, 84] Most of the work on rewriting has centered on confluence and termination. [70] Narrowing has been developed by Slagle [94]. Sequential strategies were developed by Huet and Levy [55], who gave a decidable criteria for a subset of sequential systems. This led to the work of Antoy on inductively sequential systems [8]. The needed narrowing strategy came from Hanus, Antoy, and Echahed [11]. Graph rewriting is a bit more disconnected. Currently there is not a consensus on how to represent graphs mathematically. We went with the presentation in [36], but there are also alternatives in [24, 70, 85].

Here we saw how we can rewrite terms and graphs. We will use this idea in the next chapter to rewrite entire programs. This will become the semantics for our language. Now that we have some tools, it is time to find out how to make Curry!
CHAPTER 3
THE CURRY LANGUAGE AND IMPLEMENTATION

The Curry language grew out of the efforts to combine the functional and logic pro-
gramming paradigms [51]. Originally there were two approaches to combine these
paradigms, adding functional features to logic languages, and adding logic features
to functional languages. The former approach was very popular and spawned sev-
eral new languages including Ciao-Prolog [54], Mercury [95], HAL [35], and Oz [92].
The extension of functional languages led to fewer new languages, but it did lead
to libraries like the logict monad in Haskell [69].

Ultimately the solution came from the work on automated theorem proving [94].
Instead of adding features from one paradigm to another, it was discovered that
narrowing was a good abstraction for combining the features from both paradigms.
This spawned the Curry [50] and Toy [30] languages.

In this chapter we explore the Curry language syntax and semantics. We give
example programs to show how programming in Curry differs from Prolog and
Haskell. Then we discuss the choices we made in our implementation compared
to previous implementations. Finally we give an example of generated code to
demonstrate how we compile Curry programs.

3.1 THE CURRY LANGUAGE

In order to write a compiler for Curry, we need to understand what sets Curry apart
from other programming languages. We will start by looking at some examples of
Curry programs. We will see how Curry programs differ from Haskell and Prolog
programs. We start with a simple first order functional language, and show how
adding higher-order functions, non-determinism, and free variables all affect the semantics. Then we discuss an improvement to backtracking that can increase performance significantly. Finally we discuss the effect of collapsing functions, that is functions that may return a single variable.

Curry combines the two most popular paradigms of declarative programming: Functional languages and logic languages. Curry programs are composed of defining equations like Haskell or ML, but we are allowed to have non-deterministic expressions and free variables like Prolog. This will not be an introduction to modern declarative programming languages. The reader is expected to be familiar with functional languages such as Haskell or ML, and logic languages such as Prolog. For an introduction to programming in Curry see [15]. For an exhaustive explanation of the syntax and semantics of Curry see [37].

To demonstrate the features of Curry, we will examine a small Haskell program to permute a list. Then we will simplify the program by adding features of Curry. This will demonstrate the features of Curry that we need to handle in the compiler, and also give a good basis for how we can write the compiler.

First, let us consider an example of a permutation function. This is not the only way to permute a list in Haskell, and you could easily argue that it is not the most elegant way, but we chose it for three reasons. There is no syntactic sugar, and the only two library functions are `concat` and `map`, both very common functions, and the algorithm for permuting a list is similar to the algorithm we will use in Curry.

\[
\text{perms} \quad :: \ [a] \rightarrow [[a]] \\
\text{perms} \ [\] = [[\]] \\
\text{perms} \ (x : xs) = \text{concat} \ (\text{map} \ (\text{insert} \ x) \ (\text{perms} \ xs)) \\
\]

\textbf{where}

\[
\text{insert} \ x \ [\] = [[x]] \\
\text{insert} \ x \ (y : ys) = (x : y : ys) : \text{map} \ (\text{y} : ) \ (\text{insert} \ x \ ys) \\
\]

The algorithm itself is broken into two parts. The \textit{insert} function will return a list of lists, where \(x\) is inserted into \(ys\) at every possible position. For example: \textit{insert} 1 \[2, 3\] returns \[[[1, 2, 3], [2, 1, 3], [2, 3, 1]]\]. The \textit{perms} function splits the list into a head \(x\) and tail \(xs\). First, it computes all permutations of \(xs\), then it will insert \(x\) into every possible position of every permutation.

While this algorithm is not terribly complex, it is really more complex than it needs to be. The problem is that we need to keep track of all of the permutations we generate. This does not seem like a big problem here. We just put each permutation in a list, and return the whole list of permutations. However, now every part of the program has to deal with the entire list of results. As our programs grow, we will need more data structures for this plumbing, and this problem will grow too. This is not new. Many languages have spent a lot of time trying to resolve this issue. In fact, several of Haskell’s most successful concepts, such as monads, arrows, and lenses, are designed strictly to reduce this sort of plumbing.

We take a different approach in Curry. Instead of generating every possible permutation, and searching for the right one, we will non-deterministically generate a single permutation. This seems like a trivial difference, but its really quite substantial. We offload generating all of the possibilities onto the language itself.

We can simplify our code with the non-deterministic \textit{choice} operator \(?\). Choice is defined by the rules:
\[ x \cdot y = x \]
\[ x \cdot y = y \]

Now our permutation example becomes a little easier. We only generate a single permutation, and when we insert \( x \) into \( ys \), we only insert into a single arbitrary position.

\[
\text{perm} :: [a] \to [a] \\
\text{perm} [] = [] \\
\text{perm} (x : xs) = \text{insert} \ x \ \text{perm} \ xs
\]

\text{where}

\[
\text{insert} \ x \ [] = [x] \\
\text{insert} \ x \ (y : ys) = x : y : ys \ ? y : \text{insert} \ x \ ys
\]

In many cases functions that return multiple results can lead to much simpler code. Curry has another feature that is just as useful. We can declare a free variable in Curry. This is a variable that has not been assigned a value. We can then constrain the value of a variable later in the program. In the following example \( \text{begin} \), \( x \), and \( \text{end} \) are all free variables, but they are constrained by the guard so that \( \text{begin} \ # [x] \ # \text{end} \) is equal to \( xs \). Our algorithm then becomes: pick an arbitrary \( x \) in the list, move it to the front, and permute the rest of the list.

\[
\text{perm} :: [a] \to [a] \\
\text{perm} [] = [] \\
\text{perm} \ xs \\
\begin{array}{l}
| \text{xs} == (\text{begin} \ # [x] \ # \text{end}) = x : \text{perm} (\text{begin} \ # \text{end}) \\
\text{where} \ \text{begin}, x, \text{end} \ \text{free}
\end{array}
\]

Look at that. We have reduced the number of lines of code by 25%. In fact, this pattern of declaring free variables, and then immediately constraining them is
used so often in Curry that we have syntactic sugar for it. A functional pattern is any pattern that contains a function that is not at the root\footnote{We can use functional patterns to simplify our \textit{perm} function even further.}

\begin{verbatim}
perm :: [a] → [a]
perm [] = []
perm (begin ++ [x] ++ end) = x : perm (begin ++ end)
\end{verbatim}

Now the real work of our algorithm is a single line. Even better, it is easy to read what this line means. Decompose the list into \textit{begin}, \textit{x}, and \textit{end}, then put \textit{x} at the front, and permute \textit{begin} and \textit{end}. This is almost exactly how we would describe the algorithm in English.

There is one more important feature of Curry. We can let expressions fail. In fact we have already seen it, but a more explicit example would be helpful. We have shown how we can generate all permutations of a list by generating an arbitrary permutation, and letting the language take care of the exhaustive search. However, we usually do not need, or even want, every permutation. So, how do we filter out the permutations we do not want? The answer is surprisingly simple. We just let expressions fail. An expression fails if it cannot be reduced to a constructor form. The common example here is \textit{head} [], but a more useful example might be sorting a list. We can build a sorting algorithm by permuting a list, and only keeping the permutation that is sorted.

\footnote{This is not completely correct. While the above code would fully evaluate the list, a functional pattern is allowed to be more lazy. Since the elements do not need to be checked for equality, they can be left unevaluated.}
sort :: (Ord a) ⇒ [a] → [a]

sort xs | sorted ys = ys

where

ys = perm xs

sorted [] = True

sorted [x] = True

sorted (x : y : ys) = x ≤ y ∧ sorted (y : ys)

In this example every permutation of xs that is not sorted will fail in the guard. Once an expression has failed, computation on it stops, and other alternatives are tried. As we will see later on, this ability to conditionally execute a function will become crucial when developing optimizations.

These are some of the useful programming constructs in Curry. While they are convenient for programming, we need to understand how they work if we are going to implement them in a compiler.

3.2 SEMANTICS

As we have seen, the syntax of Curry is very similar to Haskell. Functions are declared by defining equations, and new data types are declared as algebraic data types. Function application is represented by juxtaposition, so \( f \ x \) represents the function \( f \) applied to the variable \( x \). Curry also allows for declaring new infix operators. In fact, Curry really only adds two new pieces of syntax to Haskell, \texttt{fcase} and \texttt{free}. However, the main difference between Curry and Haskell is not immediately clear from the syntax. Curry allows for overlapping rules and free variables. Specifically Curry programs are represented as Limited Overlapping Inductively Sequential (LOIS) Rewrite systems. These are indicatively sequential systems with a single overlapping rule. On the other hand, Haskell programs are transformed into non-overlapping systems.
To see the difference consider the usual definition of factorial.

\[
\text{fac} :: \text{Int} \rightarrow \text{Int} \\
\text{fac} 0 = 1 \\
\text{fac} n = n \times \text{fac} (n - 1)
\]

This seems like an innocuous Haskell program, however it is non-terminating for every possible input for Curry. The reason is that \text{fac} 0 could match either rule. In Haskell all defining equations are ordered sequentially, which results in control flow similar to the following C implementation.

```c
int fac(int n) 
{
    if(n == 0) 
    { 
        return 1; 
    }
    else 
    { 
        return n * fac(n-1); 
    }
}
```

In fact, every rule with multiple defining equations follows this pattern. In the following equations let \( p_i \) be a pattern and \( E_i \) be an expression.

\[
f p_1 = E_1 \\
f p_2 = E_2 \\
\ldots \\
f p_n = E_n
\]

Then this is semantically equivalent to the following.
Here \( \neg p_i \) means that we do not match pattern \( i \). This ensures that we will only ever reduce to a single expression. Specifically we reduce to the first expression where we match the pattern.

Curry rules, on the other hand, are unordered. If we could match multiple patterns, such as in the case of \( \text{fac} \), then we non-deterministically return both expressions. This means that \( \text{fac} \, 0 \) reduces to both 1 and \( \text{fac} \, (-1) \). Exactly how Curry reduces an expression non-deterministically will be discussed throughout this dissertation, but for now we can think in terms of sets. If the expression \( e \rightarrow e_1 \) and \( e \rightarrow e_2 \), \( e_1 \rightarrow^* v_1 \) and \( e_2 \rightarrow^* v_2 \), then \( e \rightarrow^* \{ v_1, v_2 \} \).

This addition of non-determinism can lead to problems if we are not careful. Consider the following example:

\[
\begin{align*}
\text{coin} &= 0 ? 1 \\
\text{double } x &= x + x
\end{align*}
\]

We would expect that for any \( x \), \( \text{double } x \) should be an even number. However, if we were to rewrite \( \text{double } \text{coin} \) using ordinary term rewriting, then we could have the derivation.

\[
\text{double } \text{coin} \Rightarrow \text{coin} + \text{coin} \Rightarrow (0 ? 1) + (0 ? 1) \Rightarrow 0 + (0 ? 1) \Rightarrow 0 + 1 \Rightarrow 1
\]

This is clearly not the derivation we want. The problem here is that when we reduced \( \text{double } \text{coin} \), we made a copy of the non-deterministic expression \( \text{coin} \).

\footnote{This should really be thought of as a multiset, since it is possible for \( v_1 \) and \( v_2 \) to be the same value.}
This ability to clone non-deterministic expressions to get different answers is known as run-time choice semantics. \[58\].

The alternative to this is call-time choice semantics. When a non-deterministic expression is reduced, all instances of the expression take the same value. One way to enforce this is to represent expressions as graphs instead of terms. Since no expressions are ever duplicated, all instances of `coin` will reduce the same way. This issue of run-time choice semantics will appear throughout the compiler.

### 3.2.1 FlatCurry

The first step in the compiler pipeline is to parse a Curry program into FlatCurry. The definition is given in Figure 3.17. The FlatCurry language is the standard for representing Curry programs in compilers \[19,26,28,38\], and has been used to define the semantics of Curry programs \[3\].

The semantics of Curry have already been studied extensively \[3\], so we informally recall some of the more important points. A FlatCurry program consists of datatype and function definitions. For simplicity we assume that all programs are self contained, because the module system is not relevant to our work. However, the Rice compiler does support modules. A FlatCurry function contains a single rule, which is responsible for pattern matching and rewriting an expression. Pattern matching is converted into case and choice expressions as defined in \[3\]. A function returns a new expression graph constructed out of `let`, `free`, \(f_k\), \(C_k\), `?`, `l`, `v` expressions.

Our presentation of FlatCurry differs from \[3\] in three notable ways. First, function and constructor applications contain a count of the arguments they still need in order to be fully applied. The application \(f_k \ e_1 \ e_2 \ldots \ e_n\) means that \(f\) is applied to \(n\) arguments, but it needs \(k\) more to be fully applied, so the arity of \(f\) is \(n + k\). Second, we include `let \{v\} free` to represent free variables. This was not needed in \[3,28\] because free variables we translated to non-deterministic
generators. Since we narrow free variables instead of doing this transformation, we must represent free variables in FlatCurry. Finally, we add an explicit failure expression \(\bot\) to represent a branch that is not present in the definitional tree. While this is meant to simply represent a failing computation, we have also occasionally found it useful in optimization.

3.2.2 Evaluation

Each program contains a special function \(\textit{main}\) that takes no arguments. The program executes by reducing the expression \(\textit{main}\) to a Constructor Normal Form\(^6\) as defined in Figure 3.18. Similar to Kics2, Pakcs, and Sprite, we compute constructor normal form by first reducing the \(\textit{main}\) to Head Constructor Form. That is where the expression is rooted by a constructor. Then each child of the root is reduced to constructor normal form.

Most of the work of evaluation is reducing an expression to head constructor form. Kics2 and Pakcs are able to transform FlatCurry programs into an equivalent rewrite system, and reduce expressions using graph rewriting\(^{28,38}\). The transformation simply created a new function for every nested case expression. This created a series of tail calls for larger functions.

To see this transformation in action, we can examine the FlatCurry function \(==\) on lists\(^{3.19}\). This function is inductively sequential, however both Pakcs and Kics2 will transform it into a series of flat function calls with a single case at the root. Since this would drastically increase the number of function calls, we avoid this transformation. It would also defeat much of the purpose of an optimizing compiler if we were not allowed to inline functions.

\(^6\)This is constructor normal form, and not simply a normal form, because a failing expression, like \(\textit{head} []\), is a normal form, since it can not be rewritten, but it contains a function at the root.
\[ f \Rightarrow f \overline{v} = e \]

\[ e \Rightarrow v \quad \text{Variable} \]
\[ \mid l \quad \text{Literal} \]
\[ \mid e_1 \, ? \, e_2 \quad \text{Choice} \]
\[ \mid \bot \quad \text{Failed} \]
\[ \mid f_k \, \overline{v} \quad \text{Function Application} \]
\[ \mid C_k \, \overline{v} \quad \text{Constructor Application} \]
\[ \mid \text{let } \overline{v} = \overline{e} \text{ in } e \quad \text{Variable Declaration} \]
\[ \mid \text{let } \overline{v} \text{ free in } e \quad \text{Free Variable Declaration} \]
\[ \mid \text{case } e \text{ of } p \rightarrow e \quad \text{Case Expression} \]

\[ p \Rightarrow C \, \overline{v} \quad \text{Constructor Pattern} \]
\[ \mid l \quad \text{Literal Pattern} \]

Figure 3.17: Syntax definition for FlatCurry

This is largely the same as other presentations \[3, 16\] but we have elected to add more information that will become relevant for optimizations later. The notation \( \overline{v} \) refers to a variable length list \( e_1 \, e_2 \ldots \, e_n \).

\[ n \Rightarrow l \quad \text{literal} \]
\[ \mid C_k \, \overline{n} \quad \text{constructor} \]

Figure 3.18: constructor normal forms in FlatCurry.

A CNF is an expression that contains only constructor and literal symbols. All CNFs are normal forms in our system.
Original FlatCurry representation of \(==\) on lists.

\[
\text{(==) } v_2 \space v_3 = \text{case } v_2 \text{ of } \\
\text{[]} \rightarrow \text{case } v_3 \text{ of } \\
\text{[]} \rightarrow \text{True} \\
v_4 : v_5 \rightarrow \text{False} \\
v_6 : v_7 \rightarrow \text{case } v_3 \text{ of } \\
\text{[]} \rightarrow \text{False} \\
v_8 : v_9 \rightarrow v_8 == v_9 \land v_7 == v_9
\]

Transformed FlatCurry representation of \(==\) on lists.

\[
\text{(==) } v_2 \space v_3 = \text{case } v_2 \text{ of } \\
\text{[]} \rightarrow eqListNil \space v_3 \\
v_6 : v_7 \rightarrow eqListCons \space v_3 \space v_6 \space v_7 \\
\text{eqListNil } v_3 = \text{case } v_3 \text{ of } \\
\text{[]} \rightarrow \text{True} \\
v_4 : v_5 \rightarrow \text{False} \\
\text{eqListCons } v_3 \space v_6 \space v_7 = \text{case } v_3 \text{ of } \\
\text{[]} \rightarrow \text{False} \\
v_8 : v_9 \rightarrow v_8 == v_9 \land v_7 == v_9
\]

Figure 3.19: Transformation of FlatCurry \(==\) function into a flat representation for Pakcs and Kics2.
3.2.3 Non-determinism

Currently there are three approaches to evaluating non-deterministic expression in Curry: backtracking, Pull-Tabbing [7], and Bubbling [9]. At this time there are no complete strategies for evaluating Curry programs, so we have elected to use backtracking. It is the simplest to implement, and it is well understood.

In our system, backtracking is implemented in the usual way. When an expression rooted by a node $n$ with label by $f$ is rewritten to an expression rooted by $e$, we push the rewrite $(n, n_f, \text{Continue})$ onto a backtracking stack, where $n_f$ is a copy of the original node labeled by $f$. If the expression is labeled by a choice $e_1 \ ? \ e_2$, and it is rewritten to the left hand side $e_1$, then we push $(n, n_2, \text{Stop})$ onto the backtracking stack to denote that this was an alternative, and we should stop backtracking.

Unfortunately, while backtracking is well defined for rewriting systems, our representation of FlatCurry programs is not a graph rewrite system. This is because we do not flatten our FlatCurry functions like Pakcs and Kics2. As an example of why FlatCurry programs are not a graph rewriting system, consider the FlatCurry function `weird` 3.20. This function defines a local variable $x$ which is used in a case expression. If this were a rewrite system, then we would be able to translate the case expression into pattern matching, but a rule can not pattern match on a locally defined variable. We show the reduction of `weird` in Figure 3.21.

We have entered an infinite loop of computing the same rewrite. The problem is that when we were backtracking, and replacing nodes with their original versions, we were going too far back in the computation. In this example, when backtracking `weird`, we want to backtrack to a point where $x$ has been created, and we just want to evaluate the case again.

We solve this problem by creating a new function for each case expression in our original function. Figure 3.22 show an example for `weird` and `==` which were defined above. This is actually very similar to how Pakcs and Kics2 transformed
weird = let x = False ? True

    in case x of
    False \rightarrow True
    True \rightarrow False

Figure 3.20: The function *weird*

This can not be expressed as rewrite rules, because the expression we are pattern matching on is defined locally.

their programs into rewrite systems by flattening them. The difference is that we do not need to make any extra function calls unless we are already backtracking. There is no efficiency cost in either time or space with our solution. The only cost is a little more complexity in the code generator, and an increase in the generated code size. This seems like an acceptable trade off, since our programs are still similar in size to equivalent programs compiled with GHC.

As far as we are aware, this is a novel approach for improving the efficiency of backtracking in rewriting systems. The correctness of this method follows from the redex contraction theorem, which is proved later.

### 3.2.4 Free Variables

Free variables are similar to non-deterministic expressions. In fact, in both Kics2 and Sprite [19,28] they are replaced by non-deterministic generators of the appropriate type [12]. However, in Rice, free variables are instantiated by narrowing. If a free variable is the scrutinee of a case expression, then we push copies of the remaining patterns onto the stack along with another copy of the variable. If the free variable is replaced by a constructor with arguments, such as *Just*, then we
• We start with a root \( r \) labeled by \emph{weird}.

• Node \( n_1 \) labeled by \( ? \) is created with children [\emph{False}, \emph{True}].

• \( n_1 \) is rewritten to \emph{False} and \((n_1, \emph{True}, \emph{Stop})\) is pushed on the backtracking stack.

• \( r \) is rewritten to \emph{True} and \((r, \emph{weird}, \emph{Continue})\) is pushed on the backtracking stack.

• \( r \) is a constructor normal form.

• backtracking to the closest alternative.

• The backtracking stack is \([ (r, \emph{weird}, \emph{Continue}), (n_1, \emph{True}, \emph{Stop}) ] \).

• reduce \( r \).

• Node \( n_2 \) labeled by \( ? \) is created with children [\emph{False}, \emph{True}].

• \ldots

Figure 3.21: Evaluation of \emph{weird}
weird = let \( x = \text{False} \to \text{True} \)
in case \( x \) of
\( \text{False} \to \text{True} \)
\( \text{True} \to \text{False} \)
\( \text{weird}_1 \ x = \text{case} \ x \ of \)
\( \text{False} \to \text{True} \)
\( \text{True} \to \text{False} \)
\( (==) \ v_2 \ v_3 = \text{case} \ v_2 \ of \)
\( [\ ] \to \text{case} \ v_3 \ of \)
\( [\ ] \to \text{True} \)
\( v_4 : v_5 \to \text{False} \)
\( v_6 : v_7 \to \text{case} \ v_3 \ of \)
\( [\ ] \to \text{False} \)
\( v_8 : v_9 \to v_6==v_8 \land v_7==v_9 \)
\( \text{eqList}_1 \ v_3 = \text{case} \ v_3 \ of \)
\( [\ ] \to \text{True} \)
\( v_4 : v_5 \to \text{False} \)
\( \text{eqList}_2 \ v_6 \ v_7 \ v_3 = \text{case} \ v_3 \ of \)
\( [\ ] \to \text{False} \)
\( v_8 : v_9 \to v_6==v_8 \land v_7==v_9 \)

Figure 3.22: Functions at case for weird and == for lists.
instantiate the arguments with free variables.

```haskell
data Light = Red | Yellow | Green

change x = case x of
    Red   → Green
    Green → Yellow
    Yellow → Red
```

Figure 3.23: A simple traffic light program

This is easier to see with an example. Consider the traffic light function in Figure 3.23. The `change` function moves the light from `Red` to `Green` to `Yellow`. When calling this function with a free variable, we have the derivation below in Figures 3.24 and 3.25.

### 3.2.5 Higher Order Functions

Now that we have a plan for the logic features of Curry, we move on to higher-order functions. This subject has been extensively studied by the function languages community, and we take the approach of [62]. Higher-order functions are represented using defunctionalization [90]. Recall that in FlatCurry, an expression $f_k$ represents a partial application that is missing $k$ arguments. We introduce an `apply` function that has an unspecified arity, where `apply f_k e_1 e_2 \ldots e_n` applies $f_k$ to the arguments $e_1, e_2 \ldots e_n$.

The behavior of `apply` is specified below.
• We start with root $r$ labeled by $\text{change}$, with a child $x$ labeled by $\text{free}$.

• $x$ is rewritten to $\text{Red}$ and
  
  $$(x, \text{Green, Stop}), (x, \text{Yellow, Stop}), (x, \text{free, Continue})$$
  are all pushed on the stack

• $r$ is rewritten to $\text{Green}$, and $(r, \text{change, Continue})$ is pushed on the stack

• $r$ is a constructor normal form

• backtracking to the closest alternative

• backtracking stack is
  
  $$(r, \text{change, Continue}), (x, \text{Green, Stop}), (x, \text{Yellow, Stop}), (x, \text{free, Continue}).$$

• reduce $r$

• $x$ is labeled by $\text{Green}$

• $r$ is rewritten to $\text{Yellow}$, and $(r, \text{change, Continue})$ is pushed on the stack

• $r$ is a constructor normal form

• backtracking to the closest alternative

Figure 3.24: Evaluation of $\text{change } x$ where $x$ free
• backtracking stack is
  \[ (r, \text{change}, \text{Continue}), (x, \text{Yellow}, \text{Stop}), (x, \text{free}, \text{Continue}) \]  

• reduce \( r \)

• \( x \) is labeled by \( \text{Yellow} \)

• \( r \) is rewritten to \( \text{Red} \), and \( (r, \text{change}, \text{Continue}) \) is pushed on the stack

• \( r \) is a constructor normal form

• backtracking to the closest alternative

• backtracking stack is \[ (r, \text{change}, \text{Continue}), (x, \text{free}, \text{Continue}) \]

• Both rewrites are popped, and the stack is empty with no alternatives.

Figure 3.25: Evaluation of \( \text{change } x \text{ where } x \text{ free} \) continued
apply $f_k \ x_1 \ldots x_n$

| $k > n$ = $f_{k-n} \ x_1 \ldots x_n$
| $k == n$ = $f \ x_1 \ldots x_n$
| $k < n$ = $apply (f \ x_1 \ldots x_k) \ x_{k+1} \ldots x_n$

If the first argument $f$ of apply is not partially applied, then evaluate $f$ until it is, and proceed as above. In the case that $f$ is a free variable, then we return ⊥, because we do not support higher-order narrowing.

### 3.2.6 Backtracking Performance

Now that we have established a method for implementing non-determinism, we would like to improve the performance. Currently we push nodes on the backtracking stack for every rewrite. Often, we do not need to push most of these rewrites. Consider the following code for computing Fibonacci numbers:

```haskell
fib \ n = case \ n < 2 \ of
  True \ → \ n
  False \ → \ fib \ (n - 1) + fib \ (n - 2)

main = case \ fib \ 20 == (1 ? 6765) \ of
  True \ → \ putStrLn \ "found answer"
```

This program will compute $fib \ 20$, pushing all of those rewrites onto the stack as it does, and then, when it discovers that $fib \ 20 \neq 1$, it will undo all of those computations, only to redo them immediately afterwards! This is clearly not what we want. Since $fib$ is a deterministic function, we would like to avoid pushing these rewrites onto the stack. Unfortunately, this is not as simple as it would first seems for two reasons. First, determining if a function is non-deterministic in general is undecidable, so any algorithm we developed would push rewrites for some deterministic computations. Second, a function may have a non-deterministic
argument. For example, we could easily change the above program to:

\[
main = \text{case fib (1 ? 20)==6765 of True} \rightarrow \text{putStrLn "found answer"}
\]

Now the expression with \( fib \) is no longer deterministic. We sidestep the whole issue by noticing that while it is impossible to tell if an expression is non-deterministic at compile time, it is very easy to tell if it is at run time.

As far as we are aware, this is another novel solution. Each expression contains a Boolean flag that marks if it is non-deterministic. We called these \( \text{nondet} \) flags, and we refer to an expression whose root node is marked with a nondet flag as nondet. The rules for determining if an expression \( e \) is nondet are: if \( e \) is labeled by a choice, then \( e \) is nondet; if \( e \) is labeled by a function that has a case who is scrutinee is nondet, or is a forward to a nondet, then \( e \) is nondet; if \( e' \rightarrow^* e \) and \( e' \) is nondet, then \( e \) is nondet.

Any node not marked as nondet does not need to be pushed on the stack because it is not part of a choice, all of its case statements scrutinized deterministic nodes, and it is not forwarding to a non-deterministic node. However proving this is a more substantial problem.

We prove this for the class of limited overlapping inductively sequential graph rewriting systems, with the understanding our system is equivalent. This proof is based on a corresponding proof for set functions in Curry [13][Lemma 2]. The original proof was concerned with a deterministic derivation from an expression to a value. While the idea is similar, we do not want to necessarily derive an expression to a value. Instead we define a deterministic redex, and deterministic step below, and show that there is an analogous theorem for a derivation of deterministic steps, even if it does not compute a value.

**Definition 3.2.1.** Given a rewrite system \( R \) with fixed strategy \( \phi \), a \textit{computation space} \([13]\) of expression \( e \), \( C(e) \) is finitely branching tree defined inductively the
rule $C(e) = \langle e, C(e_1), C(e_2) \ldots C(e_n) \rangle$.

We now need the notions of a deterministic redex and a deterministic rewrite. Ultimately we want to show that if we have a deterministic reduction, then we can perform that computation at any point without affecting the results. One implication of this would be that performing a deterministic computation before a non-deterministic choice was made would be the same as performing the computation after the choice. This would justify our fast backtracking scheme, because it would be equivalent to performing the computation before the choice was made.

**Definition 3.2.2.** A redex $n$ in expression $e$ is deterministic if there is at most one rewrite rule that could apply to $e|_n$. A rewrite $e \rightarrow_n e'$ is deterministic if $n$ is a deterministic redex.

Next we rephrase our notion of nondet for a LOIS system.

**Definition 3.2.3.** Let $e \rightarrow e_1 \rightarrow \ldots v$ be a derivation for $e$ to $v$. A node $n$ in $e_i$ is nondet iff

1. $n$ is labeled by a choice.
2. A node in the redex pattern of $n$ is nondet.
3. There exists some $j < i$ where $n$ is a subexpression of $e_j$ and $n$ is nondet.

The first property is that all choice nodes are nondet. The second property is equivalent to the condition that any node that scrutinizes a nondet node should be nondet. Finally, the third property is that nondet should be a persistent attribute. This corresponds to the definition we gave for nondet nodes above.

If $n$ is a redex that is not marked as nondet, then $n$ can not be labeled by a choice. Since choice is the only rule in a LOIS system that is non-deterministic, $n$ must be a deterministic redex. We recall a theorem used to prove the correctness of set function. [13] [Def. 1, Lemma 1]
Lemma 4. Given an expression $e$ where $e \rightarrow_{n_1} e_1$ and $e \rightarrow_{n_2} e_2$, if $n_1 \neq n_2$, then there exists a $u_1$ and $u_2$ where $t_1 \rightarrow^= u_1$ and $t_2 \rightarrow^= u_2$ and $u_1 = u_2$ up to renaming of nodes.

This leads directly to our first important theorem. If $n$ is a deterministic redex in a derivation, then we can move it earlier in the derivation.

Theorem 5 (Redex Compression Theorem). If $n$ is a deterministic redex of $e$ where $n \rightarrow n'$, and $e \rightarrow e_1 \rightarrow_{n} e_2$. Then there exists a derivation $e[n \rightarrow n'] \rightarrow^= e'$ where $e_2 = e'$ up to renaming of nodes.

Proof. By definition of rewriting $e \rightarrow_n e[n \rightarrow n']$. Since $n$ is a deterministic redex, it must be the case that the redex in $e \rightarrow e_1$ was not $n$. So by the previous lemma, we can swap the order of the rewrites.

Finally we show that if $a$ is a subexpression of $e$ and $a \rightarrow^* b$ using only deterministic redexes, then $e[b \leftarrow a]$ rewrites to the same values.

Theorem 6 (Path Compression Theorem). If $a$ is a subexpression of $e$ and $a \rightarrow^* b$ using only deterministic rewrites, and $e \rightarrow e_1 \rightarrow \ldots e_n$ is a derivation where $b$ is a subexpression of $e_n$, then there is a derivation $e[b \leftarrow a] \rightarrow^* e_n$.

Proof. This follows by induction on the length of the derivation. In the base case $a = b$, and there is nothing to prove. In the inductive case $a \rightarrow_p a' \rightarrow^* b$. Since $a \rightarrow_p a'$ is deterministic by assumption, we can apply the path compression theorem and say that $e[a' \leftarrow a] \rightarrow^* e_n$. By the inductive hypotheses we can say that $e[a' \leftarrow a][b \leftarrow a'] \rightarrow^* e_n$. Therefore $e[b \leftarrow a] \rightarrow^* e_n$. This establishes our result.

3.2.7 Collapsing Functions

While the result of the previous section is great, and it allows us to avoid creating a large number of stack frames, there is a subtle aspect of graph rewriting that
gets in the way. If a node $n_1$ labeled by function $f$ is rewritten to $n_2$, then the definition of applying a rewrite rule [36] would require us to traverse the graph, and find every node that has $n_1$ as a child, and redirect that pointer to $n_2$. This is clearly inefficient, so this is not done in practice. A much faster method is to simply replace the contents, the label and children, of $n_1$ with the contents of $n_2$. This works most of the time, but we run into a problem when a function can rewrite to a single variable, such as the $id$ function. We call these functions \textit{collapsing functions}. One option to solve this problem is to evaluate the contractum to head constructor form, and copy the constructor to the root [23]. This is commonly used in lazy functional languages, however it does not work for Curry programs. Consider the expression following expression.

\[
f = \text{let } x = \text{True} \? \text{False}
\text{y} = \text{id } x
\text{in} \text{not } y\]

When $y$ is first evaluated, then it will evaluate $x$, and $x$ will evaluate to True. If we then copy the True constructor to $y$, then we have two copies of True. But, since $y$ is deterministic, we do not need to undo $y$ when backtracking. So, $y$ will remain True after backtracking, instead of returning to $id \ x$. While constructor copying is definitely invalid with fast backtracking, it is unclear if it would be valid with a normal backtracking algorithm.

We can solve this problem by using forwarding nodes, sometimes called indirection nodes [59]. The idea is that when we rewrite an expression rooted by a collapsing function, instead of copying the constructor, we just replace the root with a special forwarding node, $\text{FORWARD}(x)$, where $x$ is the variable that the function collapses to.

There is one more possibility to address before we move on. One performance optimization with forwarding nodes is \textit{path compression}. If we have a chain of
forwarding nodes

FORWARD(FORWARD(FORWARD(x))), we want to collapse this to simply
FORWARD(x). This is unequivocally invalid in non-deterministic backtracking
systems. Consider the following function.

\[ f = \text{let } x = \text{True} \implies \text{False} \]
\[ \quad y = \text{id } x \]
\[ \text{in } \text{case } y \text{ of } \]
\[ \quad \text{False } \rightarrow \text{case } x \text{ of } \]
\[ \quad \quad \text{False } \rightarrow () \]

When reducing this function, we create two forwarding nodes that are repre-
sented by the variables x and y. We refer to these nodes as FORWARD_x and
FORWARD_y respectively. So x is reduced to FORWARD_x(True), and y is re-
duced to FORWARD_y(FORWARD_x(True)). If we contract y to FORWARD_y(True),
then when we backtrack we replace x with FORWARD_x(False), and y is replaced
with id(True). The reason that y does not change to id(False) is because y has
lost its reference to x. Now, not only do we fail to find a solution for f, we have
ended up in a state where x and y have different values.

In this chapter we have discussed the Curry language, and overviewed the
semantics of Curry programs. We have shown different approaches to implementing
a system for running Curry programs, and we have discussed the choices that we
made. When a decision needed to be made, we prioritized correctness, then efficient
execution, and then ease of implementation. In the next chapter we discuss the
implementation at a low level. This will give us an idea of what the code we want
to generate should look like.
Now that we have examined all of the different choices to make in constructing a compiler, we can start to design the generated code and run-time system for the compiler. In this chapter we give examples of generated code to implement Curry functions, and discuss the low level details of the Rice run-time. We start with a first order deterministic subset of Curry, then we add higher-order function, finally we add non-determinism and free variables. Throughout this section we will use teletype font to represent generated C code to distinguish it from Curry or FlatCurry code.

We will introduce the generated code by looking at the _not_ function defined below. We choose this function, because it is small enough to be understandable, but it still demonstrates most of the decisions in designing the generated code and run-time system.

\[
\text{not } x = \text{case } x \text{ of } \\
\quad \text{False } \rightarrow \text{True } \\
\quad \text{True } \rightarrow \text{False }
\]

Before we discuss generated code, we need to discuss expressions and the run-time system for programs.

When a FlatCurry module is compiled, it is translated into a C program. Every function \( f \) defined in the FlatCurry module is compiled into a C function that can reduce an expression, rooted by a node labeled with \( f \), into head constructor form. These functions are called _f_hnf_ for historical reasons [38].
We chose C specifically for a few reasons. C is low level enough that the optimizations we apply to Curry are going to be distinct to the optimizations we apply to C. However, C is high level enough that we have several useful tools such as functions, and structs. We expect a modern optimizing compiler to remove most, if not all, of the abstractions that we use in the generated code. Finally C is easy to generate compared to a lower level language such as x86. An alternative would be to generate IR code for either LLVM, or java bytecode. We did not generate java bytecode, because the JVM is optimized for java like languages, and our compiled code doesn’t fit that model. LLVM-IR would be a good candidate for future work.

An expression in our compiled code is a rooted labeled graph. nodes in the graph are given the definition in Figure 4.26.

```c
typedef struct Node
{
    int missing;
    bool nondet;
    Symbol* symbol;
    field children[4];
} Node;
```

Figure 4.26: C Definition of a Node

A **field** is a union of a **Node** and the representations of the primitive types **Int**, **Float**, and **Char**, as well as a **field** to be described shortly. The use of fields instead of nodes for the children will be justified when we discuss primitive values and unboxing in chapter 7.3.5 The **children** field contains an array of children for this node. If a node could have more than three children, such as
a node representing the (,,,) constructor, then children[3] holds a pointer to a variable length array that holds the rest of the children. We chose to allow three children specifically, because in practice there are relatively few function with more than three arguments. Although, we have not tried to confirm that this is the optimal size for a node. This leads to non-uniform indexing into nodes. For example n->children[1] returns the second child of the node, but the sixth child must be retrieved with n->children[3].a[2]. We use a child_at macro to simplify the code, so child_at(n,5) returns the sixth child. The symbol field is a pointer to the static information of the node. This includes the name, arity, and tag for the node, as well as a function pointer responsible for reducing the node to head constructor form. We include a TAG macro to access the tag of a node. This is purely for convenience. For a node labeled by function f, this is a pointer to f_hnf. Because the calling convention is complicated, we hide this detail with an HNF macro, so HNF(f) evaluated the node labeled by f to head constructor form. The missing field represents a partial function application. If missing is greater than 0, then f is partially applied. The nondet field represents the nondet marker described in the fast backtracking algorithm.

Each function and constructor generates a set and make function. For the not function, we would generate

```c
void set_not(field root, field x);
field make_not(field x);
```

The set_not function sets the root parameter to be a not node. This is accomplished by changing the symbol and children for root. The make_not function allocates memory for a new not node.

Each program in our language defines an expression main, and runs until main is evaluated to constructor normal form. This evaluation is broken up into two pieces. The primary driver of a program is the nf function, which is responsible
for evaluating the main expression to constructor normal form. The \texttt{nf} function computes this form by first evaluating an expression to head constructor form. When an expression is in head constructor form, \texttt{nf} evaluates each subexpression to constructor normal form, producing the loop in Figure 4.27.

\begin{figure}[h]
\begin{verbatim}
void nf(field expr)
{
    HNF(expr);

    for(int i = 0; i < expr.n->symbol->arity; i++)
    {
        nf(child_at(expr, i));
    }
}
\end{verbatim}
\caption{An algorithm for reducing a node to constructor normal form.}
\end{figure}

All that is missing here is the \texttt{hnf} functions. We give a simplified version of the \texttt{not\_hnf} function in 4.28, and we will fill in details as we progress.

We can see that the main driver of this function is the \texttt{while(true)} loop. The loop looks up the tag of \texttt{x}, and if it is a function tag, when we evaluate it to head constructor form. If the tag for \texttt{x} is \texttt{FAIL}, which represents an exempt node, then we set the root to \texttt{FAIL} and return. If the tag is \texttt{Prelude_TRUE} or \texttt{Prelude_FALSE}, we set the root to the corresponding expression, and return from the loop. Finally, in order to implement collapsing functions, we introduce a \texttt{FORWARD} tag. If the tag is \texttt{FORWARD}, then we traverse the forwarding chain, and continue evaluating the \texttt{x}.

Finally, while we are evaluating the node stored in the local variable \texttt{x}, we introduce a new variable \texttt{scrutinee}. This is because if \texttt{x} evaluates to a forwarding
void Prelude_not_hnf(field root) {
    field x = child_at(root, 0);

    field scrutinee = x;
    while (true) {
        switch (TAG(scrutinee)) {
            case FAIL_TAG:
                fail(root);
                return;
            case FORWARD_TAG:
                scrutinee = child_at(scrutinee, 0);
                break;
            case FUNCTION_TAG:
                HNF(scrutinee);
                break;
            case Prelude_True_TAG:
                set_Prelude_False(root, 0);
                return;
            case Prelude_False_TAG:
                set_Prelude_True(root, 0);
                return;
        }
    }
}

Figure 4.28: Initial implementation of not
node, we need to evaluate the child of \( x \). If we were to update \( x \), and then return an expression containing \( x \) later, then we would have compressed the forwarding path. As mentioned previously, this is not valid.

At this point we have a strategy for how to compile first order deterministic Curry functions. Next we show how we handle partial application and higher-order functions.

### 4.1 Higher Order Functions

Earlier we gave an interpretation of how to handle \( \text{apply} \) nodes, but there are still a few details to work out. Recall the semantics we gave for \( \text{apply} \) nodes:

\[
\text{apply } f_k [x_1, \ldots, x_n] \\
| k > n = f_{k-n} x_1 \ldots x_n \\
| k==n = f x_1 \ldots x_n \\
| k < n = \text{apply} (f x_1 \ldots x_k) [x_{k+1}, \ldots, x_n]
\]

If \( f \) is missing any arguments, then we call \( f \) a partial application. Let us look at a concrete example. In the expression \( \text{foldr} (+_2) \), \( \text{foldr} \) is a partial application that is missing 2 arguments. We will write this as \( \text{foldr} (+_2) \bullet \bullet \) where \( \bullet \) denotes a missing argument. Now, suppose that we want to apply the following expression.

\[
\text{apply} \\
\text{foldr} 0 : \\
+ \bullet \bullet 1 \ldots
\]

Remember that each node represents either a function or a constructor, and each node has a fixed arity. For example, \( + \) has an arity of 2, and \( \text{foldr} \) has an arity of 3. This is true for every \( + \) or \( \text{foldr} \) node we encounter. However, it is not true for \( \text{apply} \) nodes. In fact, an \( \text{apply} \) node may have any positive arity. Furthermore, by definition, an \( \text{apply} \) node can not be missing any arguments. For this reason,
we use the **missing** field to hold the number of arguments the node is applied to.

The algorithm for reducing apply nodes is straightforward, but brittle. There are several easy mistakes to make here. The major problem with function application is getting the arguments in the correct positions. To help alleviate this problem we make a non-obvious change to the structure of nodes. We store the arguments in reverse order. To see why this is helpful, let us consider the `foldr` example above. But this time, decompose it into 3 apply nodes, so we have `apply (apply (apply foldr3 (+2)) 0) [1, 2, 3]`. In our innermost apply node, which will be evaluated first, we apply `foldr3` to `+2` to get `foldr2 (+2) ••`. This is straightforward. We simply put `+` as the first child. However, when we apply `foldr2 (+2) ••` to `0`, we need to put `0` in the second child slot. In general, when we apply an arbitrary partial application `f` to `x`, what child do we put `x` in? Well, if we are storing the arguments in reverse order, then we get a really handy result. Given function `f_k` that is missing `k` arguments, then `apply f_k x` reduces to `f_{k-1} x` where `x` is the `k - 1` child. The missing value for a function tells us exactly where to put the arguments. This is completely independent of the arity of the function.

\[
\begin{align*}
& \text{apply } (\text{apply } (\text{apply } (\text{foldr}_3 \bullet \bullet \bullet) (+2)) 0) [1, 2, 3] \\
& \Rightarrow \text{apply } (\text{apply } (\text{foldr}_2 \bullet (0 (+2)) 0) [1, 2, 3] \\
& \Rightarrow \text{apply } (\text{foldr}_1 \bullet (0 (+2)) [1, 2, 3] \\
& \Rightarrow \text{foldr}_0 [1, 2, 3] 0 (+2))
\end{align*}
\]

The algorithm is given in Figure 4.29. There are a few more complications to point out. To avoid complications, we assume arguments that a function is being applied to are stored in the array at `children[3]` of the apply node. That gives us the structure `apply f •• a_n \ldots a_1`. This is not done in the run-time system because it would be inefficient, but it simplifies the code for this presentation. We also make

\[\text{In reality we set missing to the negative value of the arity to distinguish an apply node from a partial application.}\]
use of the `set_child_at` macro, which simplifies setting child nodes and is similar to `child_at`. Finally, the loop to put the partial function in head constructor form uses `while(f.n->missing <= 0)` instead of `while(true)`. This is because our normal form is a partial application, which does not have its own tag.

We reduce an apply node in two steps. First get the function \( f \), which is the first child of an apply node. Then, reduce it to a partial application. If \( f \) came from a non-deterministic expression, the save the apply node on the stack. We split the second step into two cases. If \( f \) is under applied, or has exactly the right number of arguments, then copy the contents of \( f \) into the root, and move the arguments over and reduce. If \( f \) is over applied, then make a new copy of \( f \), and copy arguments into it until it is fully applied. Finally we reduce the fully applied copy of \( f \) and apply the rest of the arguments.

### 4.2 IMPLEMENTING NON-DETERMINISM

Now, we that we can reduce a higher-order functional language, we would like to extend our implementation to handle features from logic languages.

The implementation does not change too much. First we add two new tags `CHOICE` and `FREE` to represent non-deterministic choice and free variable nodes respectively. The choice nodes are treated in a similar manner to a function. We call the `choose` function to reduce a choice to HCF, and push the alternative on the stack.

The `choose` function in [4.30] reduces a choice node to head constructor form. Since choice is a collapsing rule, we return a forwarding node. The function is also responsible for keeping track of which branch of the choice we should reduce, and pushing the alternative on the backtracking stack. We accomplish this by keeping a marker in the second child of a choice node. This marker is 0 if we should reduce to the left hand side, and 1 if we should reduce to the right hand side.

Free variables are more interesting. To narrow a free variable we pick a possible
void apply_hnf(field root) {
    field f = child_at(root, 0);
    field* children = root.n->children[3].a;
    while(f.n->missing <= 0) { // Normal HNF loop }
    int nargs = -root.n->missing;
    int missing = f.n->missing;
    if(missing <= nargs) {
        set_copy(root, f);
        for(int i = nargs; i > 0; i--, missing--) {
            set_child_at(root, missing-1, children[i-1]);
        }
        root.n->missing = missing;
        if(missing == 0) { HNF(root); }
    } else {
        field newf = copy(f);
        while(missing > 0) {
            set_child_at(newf, missing-1, children[nargs-1]);
            nargs--;
            missing--; }
        newf.n->missing = 0;
        HNF(newf);
        set_child_at(root, 0, newf);
        root.n->missing = -nargs;
        apply_hnf(root);
    }
}

Figure 4.29: The apply_hnf function
void choose(field root)
{
    field choices[2] = {child_at(root,0), child_at(root,1)};
    int side = child_at(root,2).i;

    field saved;
    saved.n = (Node*)alloc(sizeof(Node));
    memcpy(saved.n, root.n, sizeof(Node));

    child_at_i(saved,2) = !side;
    stack_push(bt_stack, root, saved, side == 0);

    set_forward(root,choices[side]);
    root.n->nondet = true;
}

Figure 4.30: Implementation of choose
constructor, and replace the ` scrutinee ` node with that constructor. All arguments to the constructor are instantiated with free variables. Then, we push a rewrite on the stack to replace ` scrutinee ` with a free variable using the `push_frame` function. This is because after each possible choice has been exhausted, we want to reset this node back to a free variable in case it is used in another non-deterministic branch of the computation. Finally, for every other constructor, we push an alternative on the backtracking stack using the `push_choice` function.

The only other necessary change is to push a rewrite onto the backtracking stack when we reach either a fail, or constructor case. The `Prelude_not_1` function is a function at a case expression discussed in section 3.2.3. The changes to the `not` function are give in Figure 4.31. Due to space constraints not all sections are show. The pieces of code that do not changed are omitted and replaced with ... .

4.3 FAST BACKTRACKING

Finally we show how we implement the fast backtracking technique described earlier. The implementation actually does not change much, we simply make use of the `nondet` flag in each node. While we are evaluating ` scrutinee `, we keep track of whether or not we have seen a non-deterministic node in a local variable, and if we have, we push the root on the backtracking stack. If we have not seen a non-deterministic node, then we can simply avoid pushing this rewrite. The generated code for ` not ` is given in Figure 4.32.

In the last two chapters we have discussed the choices we have made with our generated code, and given an idea with what the generated code should look like. In some sense, we have given a recipe of how to translate Curry into C. In the next chapter we introduce the tools to make this recipe. We introduce a system for implementing transformations as rewrite rules. We then show how this system can simplify the construction of a compiler, and use it to transform FlatCurry programs into a form that is easier to optimize and compile to C.
void Prelude_not_hnf(field root) {
    field x = child_at(root, 0);
    field scrutinee = x;
    while(true) {
        switch(TAG(scrutinee)) {
            case FAIL_TAG:
                push_frame(root, make_Prelude_not_1(x));
                fail(root);
                return;
            ...
            case CHOICE_TAG:
                choose(scrutinee);
                break;
            case FREE_TAG:
                push_frame(scrutinee, free_var());
                push_choice(scrutinee, make_Prelude_False(0));
                set_Prelude_True(scrutinee, 0);
                break;
            case Prelude_True_TAG:
                push_frame(root, make_Prelude_not_1(x));
                set_Prelude_False(root, 0);
                return;
            ...
        }
    }
}

Figure 4.31: Non-deterministic Implementation of not
void Prelude_not_hnf(field root) {
...
bool nondet = false;
while(true) {
    nondet |= scrutinee->nondet;
    switch(TAG(scrutinee)) {
        case FAIL_TAG:
            if(nondet) push_frame(root, make_Prelude_not_1(x));
            fail(root);
            return;
        ...}
        case CHOICE_TAG:
            choose(scrutinee);
            nondet = true;
            break;
        case FREE_TAG:
            push_frame(scrutinee, free_var());
            push_choice(scrutinee, make_Prelude_False(0));
            set_Prelude_True(scrutinee, 0);
            nondet = true;
            break;
        case Prelude_True_TAG:
            if(nondet) push_frame(root, make_Prelude_not_1(x));
            set_Prelude_False(root, 0);
            return;
    ...} }
}

Figure 4.32: Full Implementation of not
CHAPTER 5
GENERATING AND ALTERING SUBEXPRESSIONS

In this chapter we introduce our engine for Generating and Altering Subexpressions, of the GAS system. This system proves to be incredibly versatile and is the main workhorse of the compiler and optimizer. We show how to construct, combine, and improve the efficiency of transformations, as well as how the system is implemented.

5.1 BUILDING OPTIMIZATIONS

Throughout this dissertation we look at the process of developing compiler optimizations. For our purposes we are concerned with compile time optimizations. These are transformations on a program, performed at compile time, that are intended to produce more efficient code. Most research in the Curry community has been done on run time optimizations, which are improvements to the evaluation of Curry programs. This can include the development of new rewriting strategies, or improvements to pull-tabbing and bubbling [19][20]. These improvements are important, but they are not our concern for this compiler.

Developing compile time optimizations is usually considered the most difficult aspect of writing a modern compiler. It is easy to see why. There are dozens of small optimizations to make, and each one needs to be written, shown correct, and tested.

Furthermore, there are several levels where an optimization can be applied. Some optimizations apply to a programs AST, some to another intermediate representation, some to the generated code, and even some to the run-time system.
There are even optimizations that are applied during transformations between representations. For this chapter, we will be describing a system to apply optimizations to FlatCurry programs. While this is not the only area of the compiler where we applied optimizations, it is by far the most extensive, so it is worth understanding how our optimization engine works.

This is a perfectly fine Curry program. Generally speaking, most optimizations have the same structure. Find an area in the AST where the optimization applies, and then replace it with the optimized version. As an example, consider the code for the absolute value function defined below.

\[
abs x \\
| x < 0 \quad = -x \\
| \text{otherwise} = x
\]

This will be translated into FlatCurry as

\[
abs x = \text{case} \ (x < 0) \ \text{of} \\
\quad True \rightarrow -x \\
| False \rightarrow \text{case} \ \text{otherwise} \ \text{of} \\
\quad True \rightarrow x \\
\quad False \rightarrow \bot
\]

While this transformation is obviously inefficient, it is general and has a straightforward implementation. A good optimizer should be able to recognize that \textit{otherwise} reduces to \textit{True}, and reduce the case-expression. So for this one example, we have two different optimizations we need to implement. We need to reduce \textit{otherwise} to \textit{True}, then we can reduce the second case expression to \textit{x}.

There are two common approaches to solving this problem. The first is to make a separate function for each optimization. Each function will traverse the AST and try to apply its optimization. The second option is to make a few large functions that attempt to apply several optimizations at once. There are trade-offs for each.
The first option has the advantage that each optimization is easy to write and understand. However, it suffers from a lot of code duplication, and it is not very efficient. We must traverse the entire AST every time we want to apply an optimization. Both LLVM and the JVM fall into this category [73, 86]. The second option is more efficient, and there is less code duplication, but it leads to large functions that are difficult to maintain or extend.

Using these two options generally leads to optimizers that are difficult to maintain. To combat this problem, many compilers will provide a language to describe optimization transformation. Then the compiler writer can use this domain specific language to develop their optimizations. With the optimization descriptions, the compiler can search the AST of a program to find any places where optimizations apply. However, it is difficult or impossible to write many common optimizations in this style [66].

In our solution we want the convenience and readability of writing standalone optimizations; the efficiency of conglomerate optimizations; and the ease of writing optimizations in a DSL. We have developed an approach to simplify Generating and Altering Subexpressions (GAS). Our approach was to do optimization entirely by rewriting. This has several advantages, and might be the most useful result of this work. First, developing new optimizations is simple. We can write down new optimizations in this system within minutes. It was often easier to write down the optimization and test it, than it was to try to describe the optimization in English. Second, any performance improvement we made to the optimization engine would apply to every optimization. Third, optimizations were easy to maintain and extend. If one optimization did not work, we could look at it and test it in isolation. Fourth, this code is much smaller than a traditional optimizer. This is not really a fair comparison given the relative immaturity of our compiler, but we were able to implement 16 optimizations and code transformations in under 150 lines of code. This gives a sense of scale of how much easier it is to implement optimizations
in this system. Fifth, since We are optimizing by rewrite rules, the compiler can easily output what rule was used, and the position where it was used. This is enough information to entirely reconstruct the optimization derivation. We found this very helpful in debugging. Finally, optimizations are written in Curry. We did not need to develop a DSL to describe the optimizations, and there are no new ideas for programmers to learn if they want to extend the compiler.

We should note that there are some potential disadvantages to the GAS system as well. The first disadvantage is that there are some optimizations and transformations that are not easily described by rewriting. The second is that, while we have improved the efficiency of the algorithm considerably, it still takes longer to optimize programs than we would like.

The first problem is not really a problem at all. If there is an optimization that does not lend itself well to rewriting, we can always write it as a traditional optimization. Furthermore, as we will see later, we do not have to stay strictly in the bounds of rewriting. The second problem is actually more fundamental to Curry. Our implementation relies on finding a single value from a set generated by a non-deterministic function. Current implementations are inefficient, but there are new implementations being developed [17]. We also believe that an optimizing compiler would help with this problem [76].

5.1.1 The Structure of an Optimization

The goal with GAS is to make optimizations simple to implement and easily readable. While this is a challenging problem, we can actually leverage Curry here. Remember that the semantics of Curry are already non-deterministic rewriting, so we can make each optimization a rewrite rule of a FlatCurry expression. We represent the rewrite rule as a function from Expr to Expr.

\[
\text{type } \text{Opt} = \text{Expr} \to \text{Expr}
\]
For readability we use the FlatCurry syntax defined in Figure 3.17. While this version of FlatCurry is easier to read, we will need the actual representation of FlatCurry programs to implement the compiler. This representation is given in Figure 5.33, and the transformation from the FlatCurry syntax to the FlatCurry representation is given in Figure 5.34. We can describe an optimization by simply describing what it does to each expression. As an example consider the definition for floating let-expressions:

\[
\text{float (Comb ct f (as + [Let vs e] + bs)) = Let vs (Comb ct f (as + [e] + bs))}
\]

This optimization tells us that, if an argument to a function application is a let expression, then we can move the let-expression outside. This works for let-expressions, but what if there is a free variable declaration inside of a function? We can just define that case with another rule.

\[
\text{float (Comb ct f (as + [Let vs e] + bs)) = Let vs (Comb ct f (as + [e] + bs))}
\]

\[
\text{float (Comb ct f (as + [Free vs e] + bs)) = Free vs (Comb ct f (as + [e] + bs))}
\]

This is where the non-determinism comes in. Suppose we have an expression:

\[
f (\text{let } x = 1 \text{ in } x) (\text{let } r \text{ free in } 2)
\]

This could be matched by either rule. The trick is that we do not care which rule matches, as long as they both do eventually. This could be a problem if both variables have the same name, so we enforce the condition that expressions contain no shadowing variables. We discuss this further in Chapter 5.1.5. This will be transformed into one of the following:

\[
\text{let } r \text{ free in let } x = 1 \text{ in } f x 2
\]

\[
\text{let } x = 1 \text{ in let } r \text{ free in } f x 2
\]

Either of these options is acceptable. In fact, we could remove the ambiguity by making our rules a confluent system, as shown by the code below. However, we will not worry about confluence for most optimizations.
\[
\text{float } (\text{Comb } ct \ f \ (as \ + \ [\text{Let } vs \ e] \ + \ bs)) = \text{Let } vs \ (\text{Comb } ct \ f \ (as \ + \ [e] \ + \ bs))
\]
\[
\text{float } (\text{Comb } ct \ f \ (as \ + \ [\text{Free } vs \ e] \ + \ bs)) = \text{Free } vs \ (\text{Comb } ct \ f \ (as \ + \ [e] \ + \ bs))
\]
\[
\text{float } (\text{Let } vs \ (\text{Free } ws \ e)) = \text{Free } ws \ (\text{Let } vs \ e)
\]

Great, now we can make an optimization. It was easy to write, but it is not a very complex optimization. In fact, most optimizations we write will not be very complex. The power of optimization comes from making small improvements several times.

Now that we can do simple examples, let us look at a more substantial transformation. Let-expressions are deceptively complicated. They allow us to make arbitrarily complex, mutually recursive, definitions. However, most of the time a large let expression could be broken down into several small let expressions. Consider the definition below:

```
let a = b
  b = c
  c = d + e
  d = b
  e = 1
in a
```

This is a perfectly valid definition, but we could also break it up into the three nested let expressions below.
let \( e = 1 \)

in let \( b = c \)

\[ \begin{align*}
    c &= d + e \\
    d &= b \\
    \text{in let } a &= b \\
    \text{in } a
\end{align*} \]

It is debatable which version is better coding style, but the second version is more useful for our optimizer. With the second version each let binding corresponds to a minimally sized group of variable bindings. This tells us by inspection if the bindings are mutually recursive. There are several optimizations that can be safely performed on a single, non-recursive, let bound variable. Unfortunately, splitting the let expression into blocks is not trivial. The algorithm involves making a graph out of all references in the let block, then finding the strongly connected components of that reference graph, and, finally, rebuilding the let expression from the component graph. The full algorithm is given below in Figure 5.35.

While this optimization is significantly more complicated than the \textit{float} example, we can still implement it in our system. Furthermore, we are able to factor out the code for building the graph and finding the strongly connected components. This is the advantage of using Curry functions as opposed to strict rewrite rules. We have much more freedom in constructing the right-hand side of our rules.

Now that we can create optimizations, what if we want both \textit{blocks} and \textit{float} to be able to run? This is an important part of the compilation process to get expressions into a canonical form. It turns out that combining two optimizations is simple. We just make a non-deterministic choice between them.

\[
\text{floatBlocks} = \text{float} \, ? \, \text{blocks}
\]

This is a new optimization that will apply either \textit{float} or \textit{blocks}. The optimizations

engine that follows will keep applying this optimization until it either cannot be
applied, or we reach a user specified number of iterations. We choose an optimi-
ization to apply at each iteration arbitrarily using oneValue function from the
FindAll library. The ability to compose optimizations with ∪ is the heart of the
GAS system. Each optimization can be developed and tested in isolation, then
they can be combined for efficiency.

5.1.2 An Initial Attempt

Our first attempt is quite simple, really. We pick an arbitrary subexpression with
subExpr and apply an optimization. We can then use a non-deterministic fix point
operator to find all transformations that can be applied to the current expression.
We can define the non-deterministic fix point operator using either the Findall
library, or Set Function [13,27]. The full code is given in Figure 5.36.
\[
\text{fix} :: (a \to a) \to a \to a
\]
\[
\text{fix } f \ x \\
\quad | f \ x = \emptyset = x \\
\quad | \text{otherwise } = \text{fix } f (f \ x)
\]

\[
\text{subExpr} :: \text{Expr} \to \text{Expr}
\]
\[
\text{subExpr } e = e \\
\text{subExpr } (\text{Comb } ct f \ vs) = \text{subExpr } (\text{foldr1 (\?) es}) \\
\text{subExpr } (\text{Let } vs e) = \text{subExpr } (\text{foldr1 (\?) (e : map snd es)}) \\
\text{subExpr } (\text{Free } vs e) = \text{subExpr } e \\
\text{subExpr } (\text{Or } e_1 e_2) = \text{subExpr } e_1 \ ? \text{subExpr } e_2 \\
\text{subExpr } (\text{Case } e bs) = \text{subExpr } (e : \text{map branchExpr bs})
\]

\textbf{where} \text{branchExpr } (\text{Branch } _e) = e

\[
\text{reduce} :: \text{Opt} \to \text{Expr} \to \text{Expr}
\]
\[
\text{reduce } opt \ e = \text{opt } (\text{subExpr } e)
\]

\[
\text{simplify} :: \text{Opt} \to \text{Expr} \to \text{Expr}
\]
\[
\text{simplify } opt \ e = \text{fix } (\text{reduce } opt) \ e
\]

Figure 5.36: A first attempt at an optimization engine. Pick an arbitrary subexpression and try to optimize it.
While this attempt is short and readable, there is a problem with it. It is unus-
ably slow. While looking at the code, it is pretty clear to see what the problem is.
Every time we traverse the expression, we can only apply a single transformation.
This means that if we need to apply 100 transformations, which is not uncommon,
then we need to traverse the expression 100 times.

5.1.3 A Second Attempt: Multiple Transformations Per Pass

Our second attempt runs much faster. Instead of picking an arbitrary subexpres-
sion, we choose to traverse the expression manually. Now, we can check at each
node if an optimization applies. We only need to make two changes. The biggest
is that we eliminate subExpr and change reduce to traverse the entire expression.
Now reduce can apply an optimization at every step. We have also made reduce
completely deterministic. The second change is that since reduce is deterministic,
we can change fix to be a more traditional implementation of a fix point operator.
The new implementation is given in Figure 5.37

This approach is significantly better. Aside from applying multiple rules in one
pass, we also limit our search space when applying our optimizations. While there
is still more we can do, the new approach makes the GAS library usable on larger
Curry programs, like the standard Prelude.

5.1.4 Adding More Information

Rather surprisingly our current approach is actually sufficient for compiling FlatCurry.
However, to optimize Curry we are going to need more information when we apply
a transformation. Specifically, we will be able to create new variables. To simplify
optimizations, we will require that each variable name can only be used once. Re-
gardless, we need a way to know what is a safe variable name that we are allowed
to use. We may also need to know if we are rewriting the root of an expression.
Fortunately, all we need to change is to define Opt to accept more parameters. For
fix :: (a → a) → a → a

fix f x
| f x == x = x
| otherwise = fix f (f x)

reduce :: Opt → Expr → Expr

reduce opt (Var v) = runOpts opt (Var v)
reduce opt (Lit l) = runOpts opt (Lit l)
reduce opt (Comb ct f es) = runOpts opt (Comb ct f (map (reduce opt) es))
    where es' = map (reduce opt) es
reduce opt (Let vs e) = runOpts opt Let (map runLet vs) (reduce opt e)
    where runLet (v, e) = (v, reduce opt e)
reduce opt (Free vs e) = runOpts opt (Free vs (reduce opt e))
reduce opt (Or a b) = runOpts opt (Or (reduce opt a) (reduce opt a))
reduce opt (Case e bs) = runOpts opt (Case (reduce opt e) bs')
    where runBranch (Branch p e) = Branch p (reduce opt e)
        bs' = map runBranch bs

runOpts :: Opt → Expr → Expr
runOpts opt e = case oneValue (opt e) of
    Nothing → e
    Just e' → e'

simplify :: Opt → Expr → Expr
simplify opt e = fix (reduce opt) e

Figure 5.37: A second attempt. Traverse the expression and, at each node, check if an optimization applies.
each optimization, we will pass in an \( n \mathbin{:} \text{Int} \) that represents the next variable \( v_n \) that is guaranteed to be fresh. We will also pass in a \( \text{top} \mathbin{:} \text{Bool} \) that tells us if we are at root of a function we are optimizing. We also return a pair of \((\text{Expr}, \text{Int})\) to denote the optimized expression, and the number of new variables we used.

\[
\textbf{type} \ \text{Opt} = (\text{Int}, \text{Bool}) \to \text{Expr} \to (\text{Expr}, \text{Int})
\]

If we later decide that we want to add more information, then we just update the first parameter. The only problem is, how do we make sure we are calling each optimization with the correct \( n \) and \( \text{top} \)? We just need to update \textit{reduce} and \textit{runOpt}. In order to keep track of the next available free variable we use the \textit{State} monad. We do need to make minor changes to \textit{fix} and \textit{simplify}, but this is just to make them compatible with \textit{State}. The full implementation is in Figures 5.38 and 5.39.

5.1.5 Reconstruction

Right now we have everything we need to write all of our optimizations. However, we’ve found it useful to be able to track which optimizations were applied and where they were applied. This helps with testing, debugging, and designing optimizations, as well as generating optimization derivations that we will see later in this dissertation. It is difficult to overstate just how helpful this addition was in building this compiler.

If we want to add this, then we need to make a few changes. First, we need to decide on a representation for a rewrite derivation. Traditionally a rewrite derivation is a sequence of rewrite steps, where each step contains the rule and position of the rewrite. We describe paths in Figure 5.40. To make reconstruction easier, we also include the expression that is the result of the rewrite. This gives us the type:
reduce :: Opt → Bool → Expr → State Int Expr

reduce opt top (Var v) = runOpts opt top (Var v)
reduce opt top (Lit l) = runOpts opt top (Lit l)
reduce opt top (Comb ct f es) = do es' ← mapM (reduce opt False es)
                                runOpts opt top (Comb ct f es')
reduce opt top (Let vs in e) = do vs' ← mapM runVar vs
                                e' ← mapM reduce opt False e
                                runOpts opt top (Let vs' in e')
                              where runVar (v, e) = do e' ← reduce opt False e
                                          return (v, e')
reduce opt top (Free vs e) = do e' ← reduce opt False e
                                runOpts opt top (Free vs e')
reduce opt top (Or a b) = do a' ← reduce opt False a
                           b' ← reduce opt False b
                           runOpts opt (Or a' b')
reduce opt top (Case e bs) = do e' ← reduce opt False e
                             bs' ← mapM runBranch bs
                             runOpts opt (Case e' bs')
                         where runBranch (Branch pat e) = do e' ← reduce opt False e
                                               return (Branch pat e')

Figure 5.38: A third attempt. Keep track of the next fresh variable, and if we’re at the root.
runOpts :: Opt → Bool → Expr → State Int Expr
runOpts opt top e = do v ← get
  case opt (v, top) e of
    Nothing → return e
    Just (e', dv) → do put (v + dv)
       return e'

fix :: (a → State b a) → a → b → a
fix f x s = let (x', s') = runState (f x) s
           in if x == x' then x else fix f x' s'

Figure 5.39: A third attempt. Keep track of the next fresh variable, and if we’re at the root. Continued.

type Path = [Int]
type Step = (String, Path, Expr)
type Derivation = [Step]

This leads to the last change we need to make to our Opt type. We need each optimization to also tell us its name. This is good practice in general, because it forces us to come up with unique names for each optimization.

type Opt = (Int, Bool) → Expr → (Expr, String, Int)

We only need to make a few change to the algorithm. Instead of using the State monad, we use a combination of the State and Writer monads, so we can keep track of the derivation. We have elected to call this the ReWriter monad. We add a function update :: Expr → Step → Int → ReWriter Expr that is similar to put from State. This updates the state variable, and creates a single step. The reduce
\[ \text{ndpath } e = [] \]
\[ \text{ndpath } (\text{Comb ct f es}) = \text{anymap argPath es} \]
\[ \text{where argPath } (i, e) = i : \text{ndpath } e_i \]
\[ \text{ndpath } (\text{Or } e_0 e_1) = 0 : \text{ndpath } e_0 ? 1 : \text{ndpath } e_1 \]
\[ \text{ndpath } (\text{Let } vs e_{-1}) = \text{anymap letPath es} \]
\[ \text{where letPath } (i, (\_, e)) = i : \text{ndpath } e \]
\[ \text{ndpath } (\text{Case } e \text{ of alts}) = -1 : \text{ndpath } e \]
\[ \text{where altPath } (i, \text{Branch } \_e) = i : \text{ndpath } e \]
\[ \text{anymap } f = \text{anyof } \circ \text{map } f \circ \text{zip } [1..] \]

Figure 5.40: The definition of a path for Curry expressions.
This function non-deterministically returns a path to a subexpression.
function requires few changes. We change the Boolean variable \( top \) to a more general \( Path \). Because of this change, we need to add the correct subexpression position, instead of just changing \( top \) to \( False \). The \( RunOpts \) function is similar. We just change \( top \) to a \( Path \), and check if it is null. Finally \( fix \) and \( simplify \) are modified to remember the rewrite steps we have already computed. We change the return type of \( simplify \) so that we have the list of steps. The full implementation is in Figures 5.41 and 5.42.

Now that we have computed the rewrite steps, it is a simple process to reconstruct them into a string. The \( pPrint \) function comes from the FlatCurry Pretty Printing Library.

\[
\text{reconstruct} :: \text{Expr} \rightarrow [\text{Step}] \rightarrow \text{String}
\]

\[
\text{reconstruct} \_ \[\] = ""
\]

\[
\text{reconstruct} \ e \ ((\text{rule}, p, \text{rhs}) : \text{steps}) = \begin{array}{l}
\text{let } e' = e[\text{rhs} \leftarrow p] \\
in "\Rightarrow " + \text{rule} + " " + (\text{show } p) + "\n" + \\
\text{pPrint } e' + "\n" + \\
\text{reconstruct } e' \text{ steps}
\end{array}
\]

Now that our optimization engine is running and printing out optimization derivations, there are a few tricks we can use to improve the efficiency. Remember that our optimizing engine is going to run for every optimization, so it is worth taking the time to tune it to be as efficient as possible. The first trick is really simple. We add a Boolean variable \( seen \) to the ReWriter monad. This variable starts as \( False \), and we set it to \( True \) if we apply any optimization. This avoids the linear time check for every call of \( fix \) to see if we actually ran any optimizations. The second quick optimization is to notice that variables, literals, and type expressions are never going to run an optimization, so we can immediately return in each of those cases without calling \( runOpt \). This is actually a much bigger deal than it might first appear. All of the leaves are going to either be variables, literals, or
\[
\text{reduce} :: \text{Opt} \rightarrow \text{Path} \rightarrow \text{Expr} \rightarrow \text{ReWriter} \text{ Expr} \\
\text{reduce opt p (Var v)} = \text{return (Var v)} \\
\text{reduce opt p (Lit l)} = \text{return (Lit l)} \\
\text{reduce opt p (Comb ct f es)} = \text{do es'} ← \text{mapM runArg (zip [0..] es)} \\
\hspace{1cm} \text{runOpts opt p (Comb ct f es)} \\
\hspace{1.5cm} \text{where runArg (n, e)} = \text{reduce opt (n : p) e} \\
\text{reduce opt p (Let vs e)} = \text{do vs'} ← \text{mapM runVar (zip [0..] vs)} \\
\hspace{1cm} \text{e'} ← \text{mapM reduce opt (−1 : p) e} \\
\hspace{1.5cm} \text{runOpts opt p (Let vs' e')} \\
\hspace{1.5cm} \text{where runVar (n, (v, e)) = fmap (λx → (v, x)) (reduce opt (n : p) e)} \\
\text{reduce opt p (Free vs in e)} = \text{do e' ← reduce opt (0 : p) e} \\
\hspace{1cm} \text{runOpts opt p (Free vs e')} \\
\text{reduce opt p (Or a b)} = \text{do a ← reduce opt (0 : p) a} \\
\hspace{1cm} b ← \text{reduce opt (1 : p) b} \\
\hspace{1cm} \text{runOpts opt (Or (a' ? b'))} \\
\text{reduce opt p (Case e bs)} = \text{do e' ← reduce opt (−1 : p) e} \\
\hspace{1cm} \text{bs' ← mapM runBranch (zip [0..] bs)} \\
\hspace{1cm} \text{runOpts opt (Case e' bs')} \\
\hspace{1.5cm} \text{where runBranch (n, (Branch pat e)) = fmap (Branch pat) (reduce opt (n : p) e)}
\]

Figure 5.41: The final version of GAS with reconstruction.
runOpts :: Opt \to Path \to Expr \to ReWriter Expr

runOpts opt p e = do v \leftarrow get

    case oneValue (opt (v, null p) e) of
        Nothing \rightarrow return e
        Just (e', rule, dv) \rightarrow do update (e', rule, p) dv
            return e'

fix :: (a \to ReWriter a) \to a \to Int \to [Step] \to (a, [Step])

fix f x n steps = let (x', n', steps') = runRewriter (f x) n

        in if x == x' then x else fix f x' n' (steps \++ steps')

Figure 5.42: The final version of GAS with reconstruction. Continued.

constructors applied to no arguments. For expression trees the leaves are often the majority of the nodes in the tree. Finally, we can put a limit on the number of optimizations to apply. If we ever reach that number, then we can immediately return. This can stop our optimizer from taking too much time.

Now that the GAS system is in place, we can move onto compiling FlatCurry programs. In this chapter we have introduced the GAS system that allows us to represent transformations in a simple form that is easy to extend and test. We have seen how we can represent an optimization as a function from expressions to expressions. Then we showed that we can extend this idea to create more powerful optimizations, and automatically generate optimization derivations. In the next chapter we put this system to work. Specifically, We will use the GAS system to implement several transformations to turn FlatCurry code in to a form that can be more easily compiled. Then we show how to generate efficient C code for FlatCurry programs.
In the last chapter we developed the GAS system for representing transformation. In this chapter we show an extended example of using the GAS system to transform FlatCurry programs into a canonical form. We then show how to translate these canonical programs to the ICurry intermediate representation. Finally, we compile the ICurry programs to C code, as discussed in Chapter 3.2.7.

This compiler, unsurprisingly, follows a traditional compiler pipeline. While we start with an AST, there are still five phases left before we can generate C code. First, we normalize FlatCurry to a canonical form. Second, we optimize the FlatCurry. Third, we sanitize the FlatCurry to simplify the process of generating C code. Fourth, we compile the FlatCurry to ICurry, an intermediate representation that is closer to C. Finally, we compile the ICurry to C. These steps are referred to as pre-process, optimize, post-process, toICurry, and toC within the compiler [74].

We give an example of a function as it passes through each of the stages of the compiler below. After pre-processing, the let expression has been floated to the top, and the missing branch has been filled in. After optimization, code is organized into blocks, and functions have been reduced. After post processing, let bound variables with a case expression have been factored out into their own functions. At this point the code is ready to be translated into ICurry and then C.

While there are several small details that are important to constructing a working Curry compiler, we will concern ourselves with the big picture here.

Let’s look at a simple Curry function defined below.
\[ f \ True = False \]
\[ f \ x = not (let \ y = not \ x \ in \ not \ y) \]

The FlatCurry representation of the above function is:

\[ f \ v_1 = (case \ v_1 \ of \ True \rightarrow False) ? \]
\[ (not (let \ v_2 = not \ v_1 \ in \ not \ v_2)) \]

After applying the Preprocessing transformations we have:

\[ f \ v_1 = \text{let } v_2 = not \ v_1 \]
\[ \text{in } (case \ v_1 \ of \]
\[ True \rightarrow False \]
\[ False \rightarrow ⊥) ? (not \ v_2) \]

After optimizing the function we have:

\[ f \ v_1 = \]
\[ \text{let } v_4 = case \ v_1 \ of \]
\[ True \rightarrow False \]
\[ False \rightarrow ⊥ \]
\[ \text{in } \text{let } v_5 = case \ v_1 \ of \]
\[ True \rightarrow False \]
\[ False \rightarrow True \]
\[ \text{in } v_4 \ ? \ v_5 \]

Finally, after applying the Post-processing transformations we have:
\[ f \ v_2 = \text{let} \ v_3 = f_0 \ v_2 \]
\[ \text{in let} \ v_4 = f_1 \ v_2 \]
\[ \text{in } v_3 \ ? \ v_4 \]
\[ f_0 \ v_2 = \text{fcase } v_2 \ \text{of} \]
\[ True \rightarrow False \]
\[ False \rightarrow \bot \]
\[ f_1 \ v_2 = \text{fcase } v_2 \ \text{of} \]
\[ True \rightarrow False \]
\[ False \rightarrow True \]

6.1 CANONICAL FLATCURRY

The pre-process and post-process steps of the compiler make heavy use of the GAS system, and transform the FlatCurry program into a form that is more amenable to C, including removing case and let expression from inside function applications. We will discuss the optimization phase in the next section, but for now we can see how transformations work.

Let us start with an example:

\[ 1 + \text{let } x = 3 \ \text{in } x \]

This is a perfectly fine Curry program, but C does not allow variable declarations in an expression, so we need to rewrite this Curry expression to:

\[ \text{let } x = 3 \ \text{in } 1 + x \]

We do not reduce \text{let } x = 3 \ \text{in } x \ yet, because that would be an optimization. However, this will be reduced later. We can translate the new expression to C in a direct manner. This is the purpose of the pre-process and post-process steps. We rewrite a Curry expression that does not make sense in C to an equivalent
\[ f \overline{v} = b \]

\[ s = \text{case } e \text{ of } C \overline{v} \rightarrow s \]
\[ \quad | \text{let } \overline{v} = e \text{ in } s \]
\[ \quad | \text{let } \overline{v} \text{ free in } s \]
\[ \quad | e \]

\[ e = v \]
\[ \quad | l \]
\[ \quad | f_k \overline{v} \]
\[ \quad | C_k \overline{v} \]
\[ \quad | e_1 ? e_2 \]

Figure 6.43: Canonical FlatCurry.

We split expressions into statement-like expressions \( s \), and expressions \( e \). Statement like expressions roughly correspond to control flow, and are translated to variable declaration and control flow statements in C.
Curry expression that we can translate directly to C. Most of the transformations consist of disallowing certain syntactic constructs. Canonical FlatCurry is defined in Figure 6.43.

Examples of the pre-processing transformations are presented in figures 6.46 and 6.47. We use the symbol $\Rightarrow$ for the optimization relation. The implementation is presented in Figures 6.44 and 6.45. We only show the initial implementation of an optimization that excludes the name and path, but it can be extended to the full optimization in a straightforward manner. The full implementation can be found in the src/Optimize/Preprocess.curry file at [74].

In practice several of these rules are generalized and optimized. For example let-expressions may have many mutually recursive variables, and when floating a let bound variable inward, we may want to recursively traverse the expression to find the innermost declaration possible. However, these extensions to the rules are also included in the repository [74].

While most of these transformations are simple, a few require some explanation. First we address a possible concern from the last chapter. Since we make no attempt to ensure confluence of our rewrite rules, can we be sure that our transformations are even valid? In general, no we cannot. GAS does nothing to enforce the validity of rewrites, it just applies them as it encounters an opportunity. This is a problem, because our rules as they are stated may not be valid. For example, consider the following program.

$$f \ (\text{let } x = 1 \ \text{in } x) \ (\text{let } x = 2 \ \text{in } x)$$

This could be transformed into one of the following.

$$\text{let } x = 1 \ \text{in } \text{let } x = 2 \ \text{in } f \ x \ x$$

$$\text{let } x = 2 \ \text{in } \text{let } x = 1 \ \text{in } f \ x \ x$$

Unfortunately, neither of these are correct. The solution in this case is very simple. We always enforce that variable names are unique. This is the purpose
\[\text{float (Let (as + [(x, \text{Let vs } e_1)] + bs) } e_2\] = Let ((x, e_1) : vs + as + bs) } e_2
\[\text{float (Let (as + [(x, \text{Free vs } e_1)] + bs) } e_2\] = Free vs (Let ((x, e_1) : as + bs) } e_2
\[\text{float (Or (Let vs e_1) } e_2\] = Let vs (Or e_1 } e_2)
\[\text{float (Or e_1 (Let vs e_2))}\] = Let vs (Or e_1 } e_2)
\[\text{float (Or (Free vs e_1) } e_2\] = Free vs (Or e_1 } e_2)
\[\text{float (Or e_1 (Free vs e_2))}\] = Free vs (Or e_1 } e_2)
\[\text{float (Comb ct n (as + [\text{Let vs } e] + bs))}\] = Let vs (Comb ct n (as + [e] + bs))
\[\text{float (Comb ct n (as + [\text{Free vs } e] + bs))}\] = Free vs (Comb ct n (as + [e] + bs))
\[\text{float (Case (Let vs e) alts)}\] = Let vs (Case e alts)
\[\text{float (Case (Free vs e) alts)}\] = Free vs (Case e alts)

\[\text{flatten (apply (apply f as) bs)}\] = applyf f (as + bs)
\[\text{flatten (apply (Case e bs) xs)}\] = Case e bs'
\[\text{where } bs' = [\text{Branch } p (\text{applyf } e' xs) | (\text{Branch } p e') \leftarrow bs]\]
\[\text{flatten (Case (Case e alt2) alt1)}\] = Case e bs (map addCase alt2)
\[\text{where addCase (Branch p e') = Branch p (Case e' b1)}\]

Figure 6.44: The Curry implementation for the pre-processing transformations.
blocks → (Let vs e) | changed = e'

where (e', changed) = makeBlocks vs e

alias → (Let (as ++ [(v, Var y)] ++ bs) e)
| v==y = Let (as ++ [(v, loop)] ++ bs) e
| otherwise = suby (Let (as ++ bs) e)

where loop = Comb FuncCall ("Prelude", "loop") []

suby = sub (λx → x==v then Var y else Var x)

fillCases dt → (Case e bs)
| not (null exempts) = Case e (bs ++ exempts)

where exempts = [Branch (Pattern b [])] exempt
| b ← missingBranches dt bs

Figure 6.45: The Curry implementation for the pre-processing transformations continued.

In fillCases, dt is a DataTable, which holds information about data types. The missingBranches takes a list of branches and a DataTable and returns the names of the branches that are not present. In alias the sub function applies a substitution to an expression.
Let Floating

\[
\begin{align*}
\text{let } x = & \text{ let } y = e_1 \\
& \text{ in } e_2 & \Rightarrow & \quad \text{let } y = e_1 \\
& \text{ in } e_3 \\
\text{let } x = & \text{ let } y \text{ free} \\
& \text{ in } e_1 & \Rightarrow & \quad \text{let } y \text{ free} \\
& \text{ in } e_2 \\
(\text{let } x = & e_1 \text{ in } e_2) \ ? e_3 & \Rightarrow & (\text{let } x = e_1 \text{ in } (e_2 \ ? e_3)) \\
(\text{let } x \text{ free in } & e_1) \ ? e_2 & \Rightarrow & (\text{let } x \text{ free in } (e_1 \ ? e_2)) \\
\text{let } x = & \text{ e}_1 \\
\text{ in } & e_2 & \Rightarrow & \quad \text{let } x = e_1 \\
& \text{ in } e_3 & \quad \text{let } x \text{ free} \\
& \text{ in } f \ e_2 & \quad \text{let } x \text{ free} \\
& \text{ in } f \ e & \quad \text{let } x \text{ free} \\

\text{case let } x \text{ free} \\
& \text{ in } e \text{ of } \text{alts} & \Rightarrow & \quad \text{let } x \text{ free} \\
& \text{ in case } e \text{ of } \text{alts}
\end{align*}
\]

Figure 6.46: GAS rules for putting FlatCurry programs into canonical form
Case in Case

\[ \text{case (case } e \text{ of } b_2 \to e_2) \text{ of } b_1 \to e_1 \Rightarrow \]
\[ \text{case } e_2 \text{ of } b_1 \to e_1 \}

Double Apply

\[ \text{apply (apply } f \ [x])\ [y] \Rightarrow \text{apply } f \ [x, y] \]

Case Apply

\[ \text{apply (case } e \text{ of } \text{pat } \to f) \ x \Rightarrow \text{case } e \text{ of } \text{pat } \to f \ x \]

Blocks

\[ \text{let } a = b \]
\[ b = c \]
\[ c = d + e \]
\[ d = b \]
\[ e = 1 \]
\[ \text{in } a \]

\[ \text{let } e = 1 \]
\[ \text{in let } b = c \]
\[ c = d + e \]
\[ d = b \]
\[ \text{in let } a = b \]

Alias

\[ \text{let } x = y \text{ in } e \Rightarrow e \ [x \to y] \]
\[ \text{let } x = x \text{ in } e \Rightarrow \text{let } x = \text{loop in } e \]

Case Fill

\[ \text{case } e \text{ of } \]
\[ True \to e \]
\[ False \to \bot \]

Figure 6.47: GAS rules for putting FlatCurry programs into canonical form (continued)

The notation \( \{ e \} \) refers to a vector of expressions, similar to \( \mathcal{v} \).
being the fresh variable provided to optimizations by GAS. If we ever need to create a new variable, then that is one that is guaranteed to be unique. However, it is up to the compiler writer to ensure that this constraint is enforced.

We may also have a condition of missing or extraneous case branches. This will become more of an issue when we discuss case cancelling in the next chapter, but we can sidestep the whole problem by enforcing a simple constraint. All cases must be full, that is they must contain a branch for every possible constructor, and they must not contain duplicates. The second constraint is already enforced by the front end of the Curry compiler. Duplicate cases are converted into choice expressions, however, we must fill in missing cases manually. This is the purpose of the **Case Fill** transformation, which completes the definitional tree. If we have a case with branches for constructors $C_1, C_2 \ldots C_k$, then we look up the type $T$ that all of these constructor belong to. Next we get the list $Ctrs$ of all constructors that belonging to $T$. This list will contain $C_1, C_2, \ldots C_n$, but it may contain more. For each constructor not represented in the case-expression, we create a new branch $C_i \rightarrow \bot$.

The **blocks** transformation takes a let block with multiple variable definitions, and rewrites it to a series of let blocks where all variables are split into strongly connected components. These are the smallest components that contain mutual recursion. This is not strictly necessary, but it removes the need to check for mutual recursion during the optimization phase. It will often transform a block of mutually defined variables into a cascading series of let expressions with a single variable, which will allow more optimizations to run throughout the compiler.

Finally the **alias** transformation will remove any aliased variables. If one variables is aliased to another, then it will do the substitution, but if a variable is aliased to itself, then it cannot be reduced to a normal form, so we can replace it with an infinite loop.

After running all of these transformations, our program is in canonical form,
and we may choose to optimize it, or we may skip straight to the post-processing phase. At this point we only need two transformations for post-processing however, we will need to add more to support some of the optimizations. If we ever have an expression of the form \texttt{let \( x = \text{case...} \)}, then we need to transform the case-expression into a function call. We do not do this transformation in pre-processing because we do not want to split functions apart during optimizations. The \textbf{Let-Case} transformation has a single rule given in Figure 6.48.

\begin{center}
\begin{figure}
\begin{align*}
\text{Let Case} & \quad f \ \overline{v} = \text{let } x = f_1 \ \overline{x} \\
& = \text{let } x = \text{case } e \ 	ext{of} \\
& \qquad \frac{\bar{p}_i \rightarrow e_i}{\frac{p_i \rightarrow e_i}{f_1 \ \overline{x} = \text{case } e \ 	ext{of}}} \Rightarrow \text{in } e' \\
& \text{Var Case} \quad \text{case } e \ 	ext{of} \ \text{alts} \Rightarrow \text{let } x = e \text{ in case } x \ 	ext{of} \ \text{alts} \\
& \text{Where } \overline{x} \text{ are free variables of } e \\
& \text{and } e_i.
\end{align*}
\end{figure}
\end{center}

Figure 6.48: Rule for moving a let bound case out of a function, and eliminating compound expressions in case-expressions.

Every let with a case-expression creates a new function \( f \# n \) where \( n \) is incremented every time.

Finally, in our post-processing phase we simply factor out the scrutinee of a case-expression into a variable. The transformation is straightforward. An example of a pre-process derivation is given in 6.49. At this point we are ready to transform the canonicalized FlatCurry into ICurry.
\[
powaux v_1 v_2 v_3 = \text{case } (\equiv) v_3 0 \text{ of }
\]
\[
\text{True } \rightarrow v_1
\]
\[
\text{False } \rightarrow \text{let } v_4 = \text{square } v_2 \\
\hspace{1cm} v_5 = \text{halve } v_3
\]
\[
\text{in case } (\equiv) (\text{apply (apply mod } v_3 \text{ 2) 1}) \text{ of }
\]
\[
\text{True } \rightarrow powaux ((\ast) v_1 v_2) v_4 v_5 \\
\text{False } \rightarrow powaux v_1 v_4 v_5
\]

⇒ **Double Apply** \([1, -1, -1, 0]\)

\[
powaux v_1 v_2 v_3 = \text{case } (\equiv) v_3 0 \text{ of }
\]
\[
\text{True } \rightarrow v_1
\]
\[
\text{False } \rightarrow \text{let } v_4 = \boxed{\text{square } v_2} \\
\hspace{1cm} v_5 = \boxed{\text{halve } v_3}
\]
\[
\text{in case } (\equiv) (\text{apply mod } v_3 2) 1 \text{ of }
\]
\[
\text{True } \rightarrow powaux ((\ast) v_1 v_2) v_4 v_5 \\
\text{False } \rightarrow powaux v_1 v_4 v_5
\]

⇒ **Blocks** \([1]\)

\[
powaux v_1 v_2 v_3 = \text{case } (\equiv) v_3 0 \text{ of }
\]
\[
\text{True } \rightarrow v_1
\]
\[
\text{False } \rightarrow \text{let } v_4 = \text{square } v_2
\]
\[
\text{in let } v_5 = \text{halve } v_3
\]
\[
\text{in case } (\equiv) (\text{apply mod } v_3 2) 1 \text{ of }
\]
\[
\text{True } \rightarrow powaux ((\ast) v_1 v_2) v_4 v_5 \\
\text{False } \rightarrow powaux v_1 v_4 v_5
\]

Figure 6.49: Reducing the \textit{powaux} function defined in the standard Float library.
6.2 COMPILING TO ICURRY

ICurry is meant to be a bridge between Curry code and imperative languages like C, Python, and Assembly. The let and case-expressions have been transformed into statements, and variables have been explicitly declared. All mutually recursive declarations are broken here into two steps: Declare memory for each node, then fill in the pointers. This allows us to create expression graphs with loops in them. Each function is organized into a sequence of blocks, and each block is broken up into declarations, assignments, and a single statement. A statement can either fail, return a new expression graph, or inspect a single variable to choose a case.

After we have finished transforming the FlatCurry, the transformation to ICurry is much easier to implement. The algorithm from [16], given in Figure 6.51, can be applied directly to the translated program. We show an example of translating the function $f$ from the start of the chapter into ICurry below.

The algorithm itself is broken up into 6 pieces. First $F$ Compiles a FlatCurry function into an ICurry function. Then $B$ takes the function arguments, the expression, and the root, and compiles it into a block. We factor out $B$ instead of leaving it a part of $F$ because we will be able to recursively call it to construct nested blocks. This is also why we pass in a root parameter. In subsequent calls, the scrutinee of a case expression will be set as the root. While this is not explicit in the algorithm here, in our implementation, the root of any block under a case expression is always $v_1$. This will become the variable scrutenee from the C code in Chapter 3.2.7. Next we declare variables with the $D$ function. Each variables bound by a let or free expression must be declared. We also declare a variable for the scrutinee of the case statement, if this block has one. Then, $R$ generates code for the return value. If the expression is a case, then examine the case variable and generate code for the associated blocks, otherwise we return the expression. Finally $E$ generates code for constructing a piece of the expression graph. If the expression
\[
\begin{align*}
  p & \Rightarrow t f & \quad \text{program} \\
  t & \Rightarrow C & \quad \text{datatype} \\
  f & \Rightarrow \text{name } = b & \quad \text{function} \\
  b & \Rightarrow d & \quad \text{block} \\
  \overline{a} & \quad s \\
  d & \Rightarrow \text{declare } x & \quad \text{variable declaration} \\
  & | \quad \text{declfree } x & \quad \text{free variable declaration} \\
  a & \Rightarrow v = e \\
  s & \Rightarrow \text{return } e & \quad \text{return statement} \\
  & | \quad \bot & \quad \text{failure} \\
  & | \quad \text{case } x \ of & \quad \text{case statement} \\
  & \quad C \to b \\
  e & \Rightarrow v & \quad \text{variable expression} \\
  & | \quad \text{NODE } (l, v) & \quad \text{node creation} \\
  & | \quad e_1 ? e_2 & \quad \text{choice expression} \\
  v & \Rightarrow x & \quad \text{local variable} \\
  & | \quad v [i] & \quad \text{variable access} \\
  & | \quad \text{ROOT} & \quad \text{root variable} \\
  l & \Rightarrow C_k & \quad \text{constructor label} \\
  & | \quad f_k & \quad \text{function label}
\end{align*}
\]

Figure 6.50: Abstract Syntax of ICurry
contains choices, function calls, or constructor calls, then the corresponding nodes are generated. If the expression is a variable, then it is returned. If the expression is a let or a free expression, then the principal expression is generated.

Let’s consider the function defined at the start of this chapter. After the Post-processing transformation, we had the following function.

\[
\begin{align*}
f \ v_2 &= \text{let } v_3 = f_0 \ v_2 \\
&\quad \text{in } \text{let } v_4 = f_1 \ v_2 \\
&\quad \quad \text{in } v_3 ? v_4 \\
f_0 \ v_2 &= \text{fcase } v_2 \ of \\
&\quad True \to False \\
&\quad False \to \bot \\
f_1 \ v_2 &= \text{fcase } v_2 \ of \\
&\quad True \to False \\
&\quad False \to True
\end{align*}
\]

After translating to ICurry, we have a new function were the structure is the same, but the code is in a more imperative style.
Figure 6.51: Algorithm for translating FlatCurry into ICurry
\[
f / 1 : \{
\text{declare } x_2 \\
\text{declare } x_3 \\
\text{declare } x_4 \\
x_2 = ROOT [0] \\
x_3 = f_0 (x_2) \\
x_4 = f_1 (x_2) \\
\text{return } (x_3 \ ? \ x_4)
\}
\]

\[
f_0 / 1 : \{
\text{declare } x_2 \\
x_2 = ROOT [0] \\
\text{case } x_2 \text{ of } \\
\text{True / 0 } \rightarrow \{ \\
\text{return False ()}
\}
\text{False / 0 } \rightarrow \{ \\
\text{exempt}
\}
\}
\]

### 6.3 Generating C Code

Now that we have a program in ICurry, we can translate this to C. We already have a good idea of what the C code should look like, and our ICurry structure fits closely with this. The difference is that we need to be sure to declare and allocate memory for all variables, which leads to a split in the structure of the generated code. The code responsible for creating expression graphs and declaring memory
will go in the *.h file, and the code for executing the hnf function will go in the
*.c file. This is a common pattern for structuring C and C++ code, so it is not
surprising that we take the same approach.

For each Data type $D$, we generate both a make$_D$ function and a set$_D$. The
difference is that make$_D$ will allocate memory for a new node, while set$_D$ takes
an existing node as a parameter, and transforms it to the given type of node. We
do the same thing for every ICurry function $f$, and produce a make$_f$ and set$_f$
function in C. Each node contains a symbol, that denotes the type of node, and
holds information such as the name, arity, and hnf function of the node. Along
with setting the symbol from Chapter 3.2.7 the make and set functions reset the
nondet flag to false, and set any children that were passed into the node.

The code to generate the C source file is given in Figures 6.52, 6.53, and 6.54.
This is a standard syntax directed translation. We hold off on showing the gener-
ated code for literal cases until Chapter 7.3.5 where we discuss our implementa-
on of unboxing. We also skip over the generation of the functions for case expressions
discussed in section 3.2.3. The code for this is largely the same. We just be-
gin generating code at each block inside the function, after the declarations and
assignments.

The translation is similar to how we translated from FlatCurry to ICurry.
Figure 6.52 is the main entry point. We translate the function, blocks, declarations,
and assignments. $F$ translates an ICurry function to a C function. $B$ translates
an ICurry block. Along with the block to translate, we also pass in the function
name, and current path to the block. This allows us to generate unique names
for each of the functions for case expressions. We will use this information in the
call to save, which pushes a rewrite onto the backtracking stack. The $D$ function
translates a variable declaration, and $A$ translates an assignment.

Figure 6.53 generates code for translating statements. The $S$ function trans-
lates an ICurry statement. Both return and ⊥ just set the root of the expression
to the appropriate value, but case statements require us to generate the switch case loop from Figure 4.28. Most of the loop is largely identical to the example, but to simplify the code generation process, we introduce a function save, which takes the root node, and a copy of the current function at this particular case, and pushes it on the backtracking stack. The notation $f|_p$ is read as the function with symbol $f$ at the position $p$, and is just a unique identifier for this particular case statement. We also use a helper function $FV$ to find all of the free variables in the rest of the body, since those will be needed to construct $f|_p$.

Finally Figure 6.54 translates free variables, case branches, and expressions to C. The $V$ function generates code to translate free variables. The final free variable, and the constructors containing free variables are pushed on the stack in reverse order. Then we set the root to be the first constructor. The $C$ function translates a case branch to a C case statement. We insert the check and call to the save function, and generate code for the block. We split the generation of expressions into two functions. The $E_S$ function sets the root to an expression. The $E_M$ function creates nodes for a new expression.

In this chapter we used this library to transform FlatCurry programs into a canonical form that we could then translate to ICurry. We also showed how to translate ICurry program to C. In short we wrote the back end of a compiler in a simple, clear, and short implementation. This shows the power of the GAS system for applying simple transformations to Curry programs. In the next chapter we will see how we can use it to write an Optimizer. Now we’re cooking with GAS!
\[ \mathcal{F}(f(\mathbf{v}) = b) := \text{void } f\_hnf(\text{field root}) \]
\[
\quad \{ \\
\quad \quad \mathcal{B}(b, f, e) \\
\quad \}
\]
\[ \mathcal{B}(\{\mathbf{d}; \mathbf{a}; \mathbf{s}\}, f, p) := \mathcal{D}(\mathbf{d}) \]
\[
\quad \mathcal{A}(\mathbf{a}) \\
\quad \mathcal{S}(\mathbf{s}, f, p)
\]
\[ \mathcal{D}(\text{declare } x) := \text{field } v.x; \]
\[ \mathcal{D}(\text{declfree } x) := \text{field } v.x = \text{free_var();} \]
\[ \mathcal{A}(x = e) := v.x = \mathcal{E}_M(e); \]
\[ \mathcal{A}(x[i] = e) := \text{child_at}(v.x, i) = \mathcal{E}_M(e); \]
\[ \mathcal{S}(\text{return } e, f, p) := \mathcal{E}_S(\text{root}, e) \]
\[
\quad \text{return; }
\]
\[ \mathcal{S}(\bot, f, p) := \text{fail(\text{root});} \]
\[
\quad \text{return; }
\]

Figure 6.52: Code for generating Programs, declarations, and assignments.
\[
S(\text{case } x \text{ of } C \to b, f, p) := \\
\text{bool nondet} = \text{false}; \\
\text{field scrutinee} = x; \\
\text{while(true)} \\
\{ \\
\text{nondet |= scrutinee.n->nondet;} \\
\text{switch(scrutinee.n->symbol->tag)} \\
\{ \\
\text{case FAIL_TAG:} \\
\text{if(nondet)} \\

Figure 6.54: Code for generating cases, free variables, and expressions.
CHAPTER 7
BASIC OPTIMIZATIONS

In the last chapter we saw how the GAS tool let us write transformation rules as rewrite rules in Curry. The power of this tool came from two aspects. The first is that it is easy to write rules syntactically. The second is that the rules are written in Curry, so we are not limited by our rewriting system. We will put this second part to use in optimizing Curry expressions.

In this chapter we outline a number of optimizations that were necessary to implement in order for unboxing, deforestation, and shortcutting to be effective. We start by introducing a new restriction on FlatCurry expressions called Administrative Normal Form, or A-Normal Form. This is a common form for functional program optimizers to take, and it provides several benefits to Curry too. We describe the transformation, and why it is useful, then we detail a few smaller optimizations that move let-expressions around. The goal is to move the let-expression to a position just before the variable is used in the expression. Finally we discuss four optimizations that will do most of the work in the compiler: Case canceling, dead code elimination, inlining, and reduction. These optimization are an important part of any optimizing compiler, but they are often tricky to get right. In fact, with the exception of dead code elimination, it is not clear at all that they are even valid for Curry. We show an effective method to implement them in a way that they remain valid for Curry expressions.

In this chapter we discuss one of the major hurdles to optimizing FlatCurry programs, we then present a solution in A-Normal form. We do on to develop some standard optimizations for FlatCurry including dead code elimination, case
canceling, and inlining. Finally, we show these optimizations at work optimizing the implementation the implementation \( \leq \) for the \( \text{Bool} \) type.

### 7.1 A-NORMAL FORM

Before we discuss any substantial optimizations, we need to deal with a significant roadblock to optimizing Curry. Equational reasoning, in the sense of replacing expressions with their derived values, is not valid when optimizing FlatCurry programs. The reason is that expressions in FlatCurry are not referentially transparent \[56\]. The evaluation of Curry programs is graph rewriting, which maintains referential transparency, but since FlatCurry is composed of terms, and not graph, we can not substitute expressions with their values.

While there have been graph intermediate representation proposed for languages \[25,48\] FlatCurry is not one of these. We do think that incorporating the graph based IR might improve the optimization process, and we believe it is a promising area of future work.

To see an example of why this an issue, let us consider the following program.

\[
\begin{align*}
\text{double } x &= x + x \\
\text{main} &= \text{double} \ (0 \ ? \ 1)
\end{align*}
\]

In pure lazy functional languages, it is always safe to replace a function with its definition. So we should be able to rewrite \text{main} to \((0?1)+(0?1)\), but this expression will produce a different set of answers. This is the primary problem with optimizing functional logic languages, but exactly why this happens is a bit tricky to pin down. The non-determinism is not the only problem, for example evaluating \text{id} \ ((0 \ ? \ 1)\) at compile time is fine. We can even duplicate non-deterministic expressions with the following example.
\[
double \ x = x + x
\]

\[
main = \text{let } y = (0 ? 1) \text{ in double } y
\]

Here \( y \) is a non-deterministic expression, because it produces two answers when evaluated, but the expression \( \text{let } y = (0 ? 1) \text{ in } y + y \) is still equivalent to our example. The real problem with our first example is a bit more subtle, and we have to step back into the world of graph rewriting. If we construct the graph for the first expression we see:

\[
\begin{align*}
double \bullet & \quad \Rightarrow \quad + \bullet \\
? \bullet & \quad \downarrow \quad ? \bullet \quad ? \bullet \\
0 \bullet & \quad 1 \bullet & \quad 0 \bullet & \quad 1 \bullet
\end{align*}
\]

Now the real issue comes to light. In the second example, while we copied a non-deterministic expression in the code, we did not copy the non-deterministic expression in the graph. This gives us a powerful tool when reasoning about Curry expressions. Even if a variable is duplicated in the source code, it is not copied in the graph. Since this duplication of non-deterministic expressions was the main concern for correctness, the solution is pretty straightforward. If we copy an expression in FlatCurry, then we should instead store that expression in a variable and copy the variable.

We can enforce this restriction by disallowing any compound expressions. Specifically, all function calls, constructor calls, choices, and case expression must either be applied to literal values or variables. Fortunately we are not the first to come
up with this idea. In fact this restricted form is used in many functional compilers, and is known as Administrative Normal Form (ANF) [41]. The idea originally was to take CPS, another well known intermediate representation for functional languages, and remove common “administrative redexes”. After removing the administrative redexes, we can remove the continuations, and rewrite the program using let-expressions. Flanagan et al. showed that these transformations can be reduced into a single A-Normal form transformation. We give the definition of A-Normal Form for Curry programs in figure 7.55 and we implement the transformation using GAS in figure 7.56 with the Curry implementation in Figure 7.57.

**ANF:**

\[
\begin{align*}
    a & \Rightarrow v & \text{Variable} \\
    | \ l & \text{Literal} \\
    | \ \bot & \text{Failed} \\
    e & \Rightarrow a_1 \ ? \ a_2 & \text{Choice} \\
    | \ f_k \ \overline{\pi} & \text{Function Application} \\
    | \ C_k \ \overline{\pi} & \text{Constructor Application} \\
    | \ \text{let} \ (\overline{v} = e) \ \text{in} \ e & \text{Variable Declaration} \\
    | \ \text{let} \ \overline{v} \ \text{free in} \ e & \text{Free Variable Declaration} \\
    | \ \text{case} \ a \ \text{of} \ \overline{\text{alt}} & \text{Case Expression}
\end{align*}
\]

Figure 7.55: Restricting Curry expressions to A-Normal Form.

An atom is either a variable, a literal, or a failure. Compound expressions are only allowed to contain atoms.

As long as we enforce this A-Normal Form structure, we restore equational reasoning for Curry programs. We do not even need to enforce A-Normal Form strictly here. During optimization, it is often useful to be able to replace variable
**Figure 7.56:** Rules for transforming Curry expression to A-Normal Form.

For any atom, an arbitrary expression, or a fresh variable name.

```plaintext
\begin{align*}
\text{case } e \text{ of } \text{alts} & \Rightarrow \text{let } x = e \text{ in case } x \text{ of } \text{alts} \\
f a_1 a_2 \ldots e_k \ldots e_n & \Rightarrow \text{let } x = e_k \text{ in } f a_1 a_2 \ldots x \ldots e_n \\
C a_1 a_2 \ldots e_k \ldots e_n & \Rightarrow \text{let } x = e_k \text{ in } C a_1 a_2 \ldots x \ldots e_n \\
e_1 ? e_2 & \Rightarrow \text{let } x = e_1 \text{ in } x ? e_2 \\
a_1 ? e_2 & \Rightarrow \text{let } x = e_2 \text{ in } a_1 ? x
\end{align*}
```

**Figure 7.57:** Curry implementation of A-Normal Form transformation.

```plaintext
toANF :: Opt
toANF (n, _) (Case ct e bs)
  | not (trivial e) = Let [(n, e)] (Case ct (Var n) bs)
toANF (n, _) (Comb ct f (as ++ [e] ++ bs))
  | all trivial as \& not (trivial e) = Let [(n, e)] (Comb ct f (as ++ [Var n] ++ bs))

toANF (n, _) (Or e_1 e_2)
  | not (trivial e_1) = Let [(n, e_1)] (Or (Var n) e_2)
  | not (trivial e_2) = Let [(n, e_2)] (Or e_1 (Var n))
```

Figure 7.57: Curry implementation of A-Normal Form transformation.
bound to constructors and partial applications with their definitions. Since these nodes have no rewrite rules that can apply at the root, we can do this replacement without fear of problems with non-deterministic expressions. This will be referred to as limited A-Normal Form.

In fact, this is exactly how the operational semantics were defined for FlatCurry. In [3] FlatCurry programs are translated into a normalized form before evaluation begins. We choose to flatten these expressions as well because it produces more uniform programs, and more optimizing transformations become valid. Some examples of programs in ANF are given in Figure 7.58.

### 7.2 CASE CANCELING

Finally, we come to our first example of an optimization. In fact, this is arguably our most important optimization. It is a very simple optimization, but it proves to be very powerful. Consider the following code:

\[
\text{notTrue} = \text{case True of} \\
\text{True} \rightarrow \text{False} \\
\text{False} \rightarrow \text{True}
\]

Expressions like this come up frequently during optimization. This is fantastic, because it is clear what we should do here. We know that the \text{True} branch will be taken, so we might as well evaluate the case expression right now.

\[
\text{notTrue} = \text{False}
\]

This transformation is called Case Canceling, and it is the workhorse of all of our other optimizations. The transformation is given and examples of the transformation are given in Figure 7.61. If the scrutinee of a case is labeled by a constructor, then we find the appropriate branch, and reduce to that branch. The only real complication is that we need to keep the expression in A-Normal form.
\( \text{fib } n = \text{case } n < 1 \) \n\( \quad \text{True } \rightarrow n \) \n\( \quad \text{False } \rightarrow \text{fib} \ (n - 1) + \) \n\( \quad \text{fib} \ (n - 2) \) \n\( \Rightarrow^* \)

\( \text{fib } n = \text{let } x = n < 1 \) \n\( \quad \text{in case } x \text{ of} \)
\( \quad \text{True } \rightarrow n \) \n\( \quad \text{False } \rightarrow \text{let } n_1 = n - 1 \) \n\( \quad n_2 = n - 2 \) \n\( \quad f_1 = \text{fib } n_1 \) \n\( \quad f_2 = \text{fib } n_2 \) \n\( \quad \text{in } f_1 + f_2 \)

\( \text{sumPrimes} = \text{let } v_1 = (+) \) \n\( \quad \text{in let } v_2 = \text{foldr } v_1 0 \) \n\( \quad \text{in let } v_3 = \text{isPrime} \) \n\( \quad \text{in let } v_4 = \text{filter } v_3 \) \n\( \quad \text{in let } v_5 = \text{enumFromTo } 1 \) \n\( \quad \text{in let } v_6 = v_4 \circ v_5 \) \n\( \quad \text{in } v_2 \circ v_6 \)

Figure 7.58: Examples of Curry programs translated to A-Normal Form.
However, we can simply add let-expressions for every variable that the constructor binds.

We also include two other optimizations. These optimizations are really about cleaning up after Case Canceling runs. The first is Case Variable elimination. Consider the expression from the optimization of compare for Bool in Figure 7.59

The use of Case Variable elimination allows us to set up a situation where a case can cancel later. This occurs a lot in practice, but this optimization may raise red flags for some. In general it is not valid to replace a variable with an expression in FlatCurry. That variable could be shared, and it could represent a non-deterministic expression. Fortunately, this is still viable in Curry.

We give a short sketch of why Case Variable elimination is viable in Curry with the following example. Suppose I have the following FlatCurry definition for \textit{notHead}. This function will look at the first element of a list, and return \textit{not True} if the head of the list evaluates to True.

\begin{verbatim}
notHead xs = case xs of 
  x:_ -> case x of 
    True -> not x
\end{verbatim}

We use a key fact from Brassels work \cite{Brassels}[Lemma 4.1.10]. Lifting a case into it is own function Does not change the set of values an expression evaluates to. We can use this to lift the inner case into it is own function.

\begin{verbatim}
notHead xs = case xs of 
  x:_ -> notHead_1 x
notHead_1 x = case x of 
  True -> not x
\end{verbatim}

Since uniform programs can be viewed as inductively sequential rewrite systems. The function \textit{notHead}_1 should be equivalent to the following Curry program.
in case \( v_2 \) of

\[ \begin{align*}
True & \rightarrow LT \\
False & \rightarrow \text{case } [v_2] \text{ of} \\
& \quad True \rightarrow EQ \\
& \quad False \rightarrow \text{case } v_1 \text{ of} \\
& \quad \quad True \rightarrow GT \\
& \quad \quad False \rightarrow EQ
\end{align*} \]

\( \Rightarrow \textbf{Case Var} \ [\!-1, 0, -1\!] \)

in case \( v_2 \) of

\[ \begin{align*}
True & \rightarrow LT \\
False & \rightarrow \text{case } [\!\text{False}\!] \text{ of} \\
& \quad True \rightarrow EQ \\
& \quad False \rightarrow \text{case } v_1 \text{ of} \\
& \quad \quad True \rightarrow GT \\
& \quad \quad False \rightarrow EQ
\end{align*} \]

\( \Rightarrow \textbf{Case Cancel} \ [\!-1, 0, -1, 1\!] \)

in case \( v_2 \) of

\[ \begin{align*}
True & \rightarrow LT \\
False & \rightarrow \text{case } v_1 \text{ of} \\
& \quad True \rightarrow GT \\
& \quad False \rightarrow EQ
\end{align*} \]

\[ \ldots \]

Figure 7.59: a piece of the optimization derivation for the implementation of \textit{compare} for \textit{Bool}. 
\[ \text{notHead}_1 \text{ True} = \text{not True} \]
\[ \text{notHead}_1 \text{ False} = \bot \]

Now this program could be compiled into the following semantically equivalent FlatCurry program.

\[ \text{notHead}_1 x = \text{case } x \text{ of} \]
\[ \quad \text{True } \rightarrow \text{not True} \]
\[ \quad \text{False } \rightarrow \bot \]

Finally, by the path compression theorem we can reduce the call in \text{notHead} to get the following result.

\[ \text{notHead } xs = \text{case } xs \text{ of} \]
\[ \quad x : \_ \rightarrow \text{case } x \text{ of} \]
\[ \quad \text{True } \rightarrow \text{not True} \]

This gives us a general procedure for converting FlatCurry programs to the same program after performing Case Variable elimination. While we do not perform these steps in practice, each one has already been shown to be valid on their own, so our transformation is also valid.

Finally we have Dead Code Elimination. This is a standard optimization. In short, if we have an empty \text{let} or \text{free} expression, then we can remove them. This may happen due to the aliasing rule from last chapter. Furthermore if a variable is never used, then it can also be removed. Finally, if we have \text{let } x = e \text{ in } x, then we do not need to create the variable \text{x}. These are correct as long as we are careful to make sure that our variable definitions are not recursive.

Now that we have finally created an optimization, we can get back to moving code around in convoluted patterns. In the next section we look at how we can inline functions. Unlike Case Canceling, It is harder to determine the correctness of Inlining. In fact, we have to do a lot of work to inline functions in Curry.
caseCancel :: Opt

\[
\text{caseCancel} \ (\text{Case} \ \text{(Comb ConsCall} \ n \ \text{es}) \ (+ [\text{Branch} \ (\text{Pattern} \ n \ \text{vs}) \ e] \ +)) = \text{foldr Let} \ e \ (\text{zip} \ \text{vs} \ \text{es})

\]

\[
\text{let } v = e \text{ in } v \mid v \not\in e \quad \Rightarrow \quad e
\]

Figure 7.61: Case Canceling, Case Variable, and Dead Code Elimination optimizations.
7.3 INLINING

As mentioned at the start of this chapter, inlining is not generally valid in Curry. So, we need to establish cases when inlining is valid, determine when it is a good idea to inline, and ensure that our inlining algorithm is correct. This work is largely based on [29,64].

Similarly to [64], we need to make a distinction between inlining and reduction. When we use the term inlining we are referring to replacing a let bound variable with its definition. For example let \( x = \text{True} \) in \( \text{not } x \) could inline to \( \text{not True} \). When we use the term reduction, we are referring to replacing a function call with the body of the function where the parameters of the function are replaced with the arguments of the call. Again, as an example let \( x = \text{True} \) in \( \text{not } x \) could reduce to:

\[
\text{let } x = \text{True} \\
\text{in case } x \text{ of} \\
\text{ True } \rightarrow \text{False} \\
\text{ False } \rightarrow \text{True}
\]

The first problem with inlining and reduction we encounter is recursion. Consider the expression:

\[
\text{let loop } = \text{loop in } \ldots
\]

If we were to inline this variable, we could potentially send the optimizer into an infinite loop. So, we need to somehow mark all recursive variables and functions. The next problem follows immediately after that. So far we have done transformations with local information, but reduction is going to require global information. In fact, for reduction to be effective, it will require information from different modules. Consider the function:

\[
\text{sumPrimes } = \text{foldr (+) 0 \circ filter isPrime \circ enumFromTo 1}
\]
Aside from the fact that \textit{sumPrimes} contains mostly recursive functions, we would not be able to optimize it anyway, because $\circ$ is defined in the standard Prelude. If we can not reduce the definition of $\circ$, then we are fighting a losing battle.

This brings us to our third problem with inlining. The \textit{sumPrimes} function is actually partially applied. Its type should be $\textit{sumPrimes} :: \text{Int} \rightarrow \text{Int}$, but \textit{sumPrimes} is defined in a point-free style. Point-free programming causes a lot of problems, specifically because FlatCurry is a combinator language. In IRs like Haskell’s Core, we could solve this problem by inlining a lambda expression, but it is not clear at all that inlining a lambda expression is valid in Curry. Instead, to solve this problem, we convert functions to be fully applied.

In order to solve these problems, we keep a map from function names to several attributes about the function. This includes: if the function is defined externally; if the function is known to be deterministic; if the function contains cases; the parameters of the function; the current number of variables in a function; the size of the function; and the function definition. This map is updated every time we optimize a new function, so we can reduce all functions that we have already optimized. We will use this map to determine when it is safe and effective to reduce a function.

### 7.3.1 Partial Applications

Dealing with partial applications is a bit more tricky. In fact, we can not use the \texttt{GAS} system to solve this problem because we may not know if a function is a partial application until we have optimized it. Consider the \textit{sumPrimes} function again. It does not look like a partial application because the root function, $\circ$, is fully applied. Let us look at the definition for $\circ$. In Curry it is defined using a lambda expression.

$$\textit{f} \circ \textit{g} = \lambda x \rightarrow \textit{f} (\textit{g} \ x)$$
However, when translated to FlatCurry, this lambda expression is turned into a combinator.

\[ f \circ g = \text{compLambda}_1 f g \]
\[ \text{compLambda} f g x = f (g x) \]

So, when we try to optimize \textit{sumPrimes} we end up with the derivation in Figure 7.62.

The \textbf{Reduce Base} and \textbf{Reduce Let} transformations will be described later. At this point there is no more optimization that can be done, because everything is a partial function. But this is not a great result. We have created a pipeline, and when we pass it a variable, then everything will be fully applied. So, how do we solve the problem?

The key is to notice that if the root of the body of a function is a partial application, then we can rewrite our definition. We simply add enough variables to the function definition so the body of the function is fully applied. The transformation

\textbf{Add Missing Variables}

\[ f \, \overline{v} = g \, k \, \overline{v} \quad \Rightarrow \quad f \, \overline{v} \, \overline{x} = \text{apply} \, (g \, k \, \overline{v}) \, \overline{x} \]

The \textit{sumPrimes} functions is transformed with the derivation in 7.63 and we can continue to optimize the function.

\subsection{7.3.2 The Function Table}

In order to keep track of all of the functions we have optimized we create a function lookup table called \( F_F \). The function table is just a map from function names to information about the function. We use the following definitions for lookups into the function table. \( I_F \) \( f \) returns true if we believe that \( f \) is a good candidate for reduction. We have designed the compiler so that whatever heuristic we use to decide if a function can be inlined, it is easy to tweak, but at the very least \( f \) should
Figure 7.62: Initial optimization of $\text{sumPrimes}$
in let $v_2 = \text{foldr}_1 (+) 0$

in let $v_6 = \text{compLambda}_1 v_4 v_5$

in \text{apply} (\text{compLambda}_1 v_2 v_6) x_1

⇒ Unapply

in let $v_2 = \text{foldr}_1 (+) 0$

... 

in let $v_6 = \text{compLambda}_1 v_4 v_5$

in \text{compLambda}_1 v_2 v_6 x_1

Figure 7.63: Adding a missing variable to \textit{sumPrimes}
not be external, nor too big, and inlining $f$ should not lead to an infinite derivation. $U_F \ x \ f \ e$ attempts to determine if reducing the function $f$ in the expression \let $x = f \ldots \in e$ would be useful. Again this heuristic is easily tweakable, but currently, a function is useful if $x$ is returned from the function, it is used as the scrutinee of a case expression, or it is used in a function that is likely to be reduced. $S_F f$ returns True if $f$ is a simple reduction with no case expressions. It is always useful to reduce these functions. $C_F f \ [e_1, \ldots e_n]$ returns true if reducing $f$ with $e_1 \ldots e_n$ will likely cause Case Canceling.

7.3.3 Function Ordering

The problem of function ordering seems like it should be pretty inconsequential, but it turns out to be very important. However, this problem has already been well studied \cite{29,64}, and the solutions for other languages apply equally well to Curry.

The problem seems very complicated at the start. We want to know what is the best order to optimize functions. Fortunately there is a very natural solution. If possible we should optimize a function before we optimize any function that calls it. This turns out to be an exercise in Graph Theory.

We define the Call Graph of a set of functions $F = \{f_1, f_2, \ldots f_n\}$ to be the graph $\Gamma_F = (F, \{f_i \rightarrow f_j | f_i \text{ calls } f_j\})$. This problem reduces to finding the topological ordering of $\Gamma_F$. Unfortunately, if $F$ contains any recursion, then the topological ordering is not defined. So, instead, we split $\Gamma_F$ into strongly connected components, and find the topological ordering of those components. Within each component, we pick an arbitrary function, called the loop breaker, which is removed from the graph. This is done with a heuristic based on the number of incoming edges in the graph, and how likely we think it is to be inlined. We then attempt to find the topological order of each component again. This process repeats until our graph is acyclic.
These loop breakers are marked in $F_r$, and they are never allowed to be reduced. Every other function can be reduced, because all functions that it calls, except for possibly the loop breakers, have been optimized.

Consider the program:

\[
\begin{align*}
f(x) &= g(x) \\
g(x) &= h(x) \\
h(x) &= \begin{cases} 
0 & \rightarrow 0 \\
- & \rightarrow 1 + f(x)
\end{cases}
\end{align*}
\]

The graph for this function is a triangle, because $f$ calls $g$ which calls $h$ which calls $f$. However, if we mark $h$ as a loop breaker, then suddenly this problem is easy. When we optimize $h$, we are free to reduce $f$ and $g$. We can see the derivation in Figure 7.64.

### 7.3.4 Inlining

Now that we have everything in order, we can start developing the inlining transformation. As mentioned before, we need to be careful with inlining. In general, unrestricted inlining is not valid in Curry. This is a large change from lazy languages like Haskell, where it is valid, but not always a good idea. The other major distinction is that FlatCurry is a combinator language. This means that we have no lambda expressions, which limits what we can even do with inlining.

Fortunately for us, these problems actually end up canceling each other out. In Peyton-Jones work [64] most of the focus was on inlining let bound variables, because this is where duplication of computation could occur. However, we have two things working for us. The first is that we can not inline a lambda since they do not exist. The second is that we have translated FlatCurry to ANormal Form.
\[
\begin{align*}
    h \ x &= \text{case } x \ \text{of} \\
    &\quad 0 \rightarrow 0 \\
    &\quad _ \rightarrow \text{let } y = f\ x \\
    &\qquad \text{in } 1 + y \\
    &\Rightarrow \text{Reduce Let} \\
    h \ x &= \text{case } x \ \text{of} \\
    &\quad 0 \rightarrow 0 \\
    &\quad _ \rightarrow \text{let } y = g\ x \\
    &\qquad \text{in } 1 + y \\
    &\Rightarrow \text{Reduce Let} \\
    h \ x &= \text{case } x \ \text{of} \\
    &\quad 0 \rightarrow 0 \\
    &\quad _ \rightarrow \text{let } y = h\ x \\
    &\qquad \text{in } 1 + y
\end{align*}
\]

Figure 7.64: Optimization of Strongly Connected Functions.
While Haskell programs are put into A-Normal Form when translating to STG code \[60\], this is not the case for Core. Certain constraints are enforced, such as the trivial constructor argument invariant, but in general Core is less restricted.

Translating to A-Normal form gives us an important result. If we inline a constructor then we do not affect the computed results. This same result holds for literal values, but we will discuss how we handle literals in Curry in the next chapter.

**Theorem 7.** If \( \text{let } x = e_1 \text{ in } e \) is a Curry expression in limited A-Normal Form, and \( e_1 \) is rooted by a constructor application, or partial application, then \( e[e_1 \leftarrow x] \) computes the same results.

**Proof.** First note that given our semantics for partial application, a partially applied function is a normal form. There are no rules for evaluating a partial application, only for examining one while evaluating an apply node.

If \( e_1 \) is a constructor, or partial application, then it is a normal form. Therefore it is a deterministic expression by definition \[3.2.6\]. Since \( e_1 \) is deterministic by the path compression theorem, \( e \) evaluates to the same values as \( e[e_1 \leftarrow x] \)

Now we have enough information to inline variables as long as we restrict inlining to literals, constructors, variables, and partial applications, although the case for variables is already subsumed by the \textbf{Alias} rule \[6.47\]. We add two new rules. \textbf{Let Folding} allows us to move variable definitions closer to where they are actually used, and \textbf{Unapply} allows us to simplify expressions involving \textit{apply}. Both of these are useful for inlining and reduction. The \textbf{GAS} rules are given in Figure \[7.65\]. Note that the \textbf{Unapply} rule corresponds exactly to the evaluation step for application nodes in our semantics. The inlining rules correspond to the cases discussed above. We add one more rule. We inline a variable bound to a case expression, if that expression occurs once in a needed position. Since we can not determine if the variable occurs in a needed position at compile time, we
can use check if it occurs in a strict position [82]. This is usually good enough. The implementation of Inlining in the GAS system is given in Figure [7.66]. The combinator $(x, e) \otimes \sigma$ is used to build up substitutions. It means that we add we add $x \rightarrow e$ to the substitution $\sigma$. The idSub substitution is just the identity. In the letFold rule, hasVar checks is expression $e$ contains variable $v$. In the fist Inlining rule, the strict and uses functions are just to ensure that $x$ is a in a strict position, and that it is only at one position in $e$. These are not required for correctness, we have found that these restrictions generate better code.

7.3.5 Reduce

Finally we come to reduction. While this was a simpler task than inlining in GHC, it becomes a very tricky prospect in Curry. Fortunately, we have already done the hard work. At this point, in any given function definition, the only place a function symbol is allowed to appear in our expressions is as the root of the body, as the root of a branch in a case expression, as the root the result of a let expression, or as a variable assignment in a let-expression. Furthermore our functions only contain trivial arguments, so it is now valid to reduce any function we come across.

**Theorem 8** (reduction). Let $e$ be an expression in limited A-Normal Form, let $e|_p = f \overline{v}$, where $f$ is a function symbol with definition $f \overline{v} = b$, and let $\sigma = \{\overline{v} \mapsto \overline{e}\}$. Then $e[\sigma b \leftarrow p]$ has the same values as $e$.

**Proof.** First note that There is only one way to replace an expression where the root has symbol $f$, with the body of the definition for $f$. Therefore This is a deterministic step, and by the path compression theorem $e$ and $e[\sigma b \leftarrow p]$ have the same values.

We give the GAS rules for reduction in Figure [7.67]. These rule make use of the function table We make sure that $B_F f$ replaces the definition with fresh variables. Therefore, we avoid any need to deal with shadowing and name capture. This
Let Folding

\[
\text{let } v = e_v \quad \text{in case } e \text{ of } C_i \overrightarrow{x} \rightarrow e_i \quad \Rightarrow \quad \text{case } e \text{ of } C_i \overrightarrow{x} \rightarrow \text{let } v = e_v \text{ in } e_i
\]

Unapply

\[
\text{apply } f_k (a_1 \ldots a_k \ldots a_n) \quad \Rightarrow \quad \text{let } x = f_0 a_1 \ldots a_k \text{ in } apply x a_{k+1} \ldots a_n
\]

\[
\text{apply } f_n (a_1 \ldots a_n) \quad \Rightarrow \quad f (a_1 \ldots a_n)
\]

\[
\text{apply } f_k (a_1 \ldots a_n) \mid k > n \quad \Rightarrow \quad f_{k-n} (a_1 \ldots a_n)
\]

Inlining

\[
\text{let } x = \text{case } e \text{ of } \text{alts} \mid x \in_1 e \quad \Rightarrow \quad e'[\text{case } e \text{ of } \text{alts} \leftarrow x]
\]

\[
\text{let } x = C \overrightarrow{v} \text{ in } e \mid x \notin e \quad \Rightarrow \quad e[C \overrightarrow{v} \leftarrow x]
\]

\[
\text{let } x = f_k \overrightarrow{v} \text{ in } e \mid x \notin e \quad \Rightarrow \quad e[f_k \overrightarrow{v} \leftarrow x]
\]

\[
\text{let } x = l \text{ in } e \quad \Rightarrow \quad e[l \leftarrow x]
\]

Figure 7.65: Rules for variable inlining.

We need to ensure that \( x \) is not used recursively before we inline it. Guards indicate that the rule fire only if the guard is satisfied. The notation \( \in_1 \) indicates that the variable \( x \) occurs exactly once in a strict position in \( e' \), so the case will be evaluated.

inline _ (Let [v@( _, Lit _ )] e) = sub (v @> idSub) e

Figure 7.66: GAS implementation of the inlining rules.
strategy was taken from [64] and it works very well. Although, since FlatCurry uses numbers exclusively to represent variables, we do not get the same readable code.

\[
\text{Reduce Base:} \quad f \overline{v} \quad \mid \quad \text{top} \quad \land \quad I_f(f) \quad \Rightarrow \quad B_f(f)[\overline{v} \leftarrow \overline{v}]
\]

\[
\text{Reduce Branch:} \quad \text{case } e' \text{ of } Ctr \rightarrow f \overline{v} \mid I_f(f) \quad \Rightarrow \quad \text{case } e' \text{ of } B_f f[\overline{v} \leftarrow \overline{v}]
\]

\[
\text{Reduce Let:} \quad \text{let } \overline{v_i} = \overline{e_i} \text{ in } f \overline{v} \mid I_f(f) \quad \Rightarrow \quad \text{let } \overline{v_i} = \overline{e_i} \text{ in } B_f f[\overline{v} \leftarrow \overline{v}]
\]

\[
\text{Reduce Useful:} \quad \text{let } x = f \overline{v} \text{ in } e' \mid U_f(f) \quad \Rightarrow \quad \text{let } x = B_f f[\overline{v} \leftarrow \overline{v}] \text{ in } e'
\]

\[
\text{Reduce Simple:} \quad \text{let } x = f \overline{v} \text{ in } e' \mid S_f(f) \quad \Rightarrow \quad \text{let } x = B_f f[\overline{v} \leftarrow \overline{v}] \text{ in } e'
\]

\[
\text{Reduce Cancels:} \quad \text{let } x = f \overline{v} \text{ in } e' \mid C_f(f) \quad \Rightarrow \quad \text{let } x = B_f f[\overline{v} \leftarrow \overline{v}] \text{ in } e'
\]

Figure 7.67: The rules for reduction.

All expressions are kept in A-Normal Form. Reduce Base is only run at the root of the body. While the last three rules are very similar, it is useful to keep them separated for debugging reduction derivations.

We end by giving a couple of examples of reductions to see how they work in practice. The first example returns from the start of this chapter. We see that \textit{double} (0 ? 1) is reduced so we do not make a needless call to \textit{double}, but we have
reduce :: FunTable → Opt
reduce funs = reduce_base funs ? reduce_branch funs
           ? reduce_let funs ? reduce_useful funs
           ? reduce_simple funs ? reduce_cancels funs
reduce_base funs (n, True) b@(Comb FuncCall f _)  
                    | inlinable funs f = makeReduce funs n b
reduce_branch funs (n, _) (Case ct e 
                        (as ++ [Branch p b@(Comb FuncCall f _)] ++ bs)) 
                    | inlinable funs f = Case ct e (as ++ [Branch p b’] ++ bs) 
                        where b’ = makeReduce funs n b
reduce_let funs (n, _) (Let vs b@(Comb FuncCall f _)) 
                    | inlinable funs f = Let vs (makeReduce funs n b)
reduce_useful funs (n, _) (Let [(x, b@(Comb FuncCall f _))] e) 
                    | inlinable funs f ∧ useful funs False x e = Let [(x, b’)] e 
                        where b’ = makeReduce funs n b
reduce_simple funs (n, _) (Let [(x, b@(Comb FuncCall f _))] e) 
                    | simple funs f = Let [(x, b’)] e 
                        where b’ = makeReduce funs n b
reduce_cancels funs (n, _) (Let [(x, b@(Comb FuncCall f es))] e) 
                    | inlinable funs f ∧ cancels funs f (map isConsExpr es) = Let [(x, b’)] e 
                        where b’ = makeReduce funs n b

avoided the problem of run time choice semantics.

Our next function comes from a possible implementation of \( \leq \) for Boolean values. In fact, this is the implementation we chose for the instance of the \textit{Ord} class for \textit{Bool}. The example is a bit long, but it shows how many of these optimizations work together to produce efficient code.

In the next chapter we discuss three more optimizations, Unboxing, Case Shortcutting, and Deforestation. While Unboxing and Deforestation are in common use in lazy function compilers, they have not been used for functional-logic languages before. Case Shortcutting is a new optimization to Curry.

\begin{verbatim}
double x = x + x
main = double (0 ? 1)
double [0 ? 1]  \Rightarrow ANF App
let v1 = 0 ? 1
in [double v1]
  \Rightarrow Reduce Let

CHAPTER 8
MEMORY OPTIMIZATIONS

In this chapter we develop three new optimizations for Curry. First, Unboxing is an attempt to remove boxed values from our language. We discuss our implementation of primitive values and operations, and how explicitly representing the boxes around these values leads to optimizations. Second, we look at an entirely new idea for removing node constructions that are quickly evaluated by case expressions that we call Case Shortcutting. Finally, Deforestation, specifically Shortcut Deforestation, is an optimization for removing intermediate lists. This has been studied extensively in functional languages, but it has not been shown to be valid in the presence of non-determinism. We prove its validity in Curry, and give a formulation that can apply to combinator languages.

8.1 UNBOXING

So far we have avoided talking about operations in Curry for primitive data types *Int*, *Char*, and *Float*. This is primarily because in all current implementations of Curry, primitive values are boxed. A *box* for a primitive value is a node in the expression graph that holds the primitive value. This is done primarily to give a uniform representation of nodes in our expression graph. There are many reasons why we would want to box primitive values. It makes the implementations of runtime systems, garbage collectors, and debugging software much easier. The choice of how we represent boxes has a pervasive effect on the compiler. Since we knew how we intended to implement Unboxing, we decided to use our representation from the beginning.
We chose to follow the style of Unboxing from Launchbury et al. \[91\] and represent all boxes explicitly in FlatCurry, as opposed to other system which may represent the boxes at run-time, but do not mention the boxes at compile time. This has several advantages, but one of the most important is that we can apply optimizations to the boxes themselves.

### 8.1.1 Boxed Values

Before we get into the process of unboxing values, we need to look at how we represent boxed values. The idea of boxing primitive values is common in higher level languages, since it allows us to simplify the run-time system. This is especially true in lazy languages where expressions such as \(3 + 5\) are represented by an expression graph that will eventually hold the value 8 after it is evaluated. It is important that every node that points to the expression graph of \(3 + 5\) at run-time will then point to the expression graph of 8 after it is evaluated. This update is difficult if 8 is the literal C integer 8. However, if 8 is instead a constructor node containing the value 8, then this is fine. We just replace the contents of the node labeled by + by a node labeled by \textit{Int} with one child, which is the C integer 8.

The purpose of unboxing is not to remove boxes entirely. Instead we try to find cases where we replace the creation of new nodes in the expression graph with primitive arithmetic operations. The idea from Launchbury \[91\] is that we can find these cases where we can remove boxes more easily if the boxes are explicitly represented in the intermediate representation. In order to represent boxes we need to make three changes to our FlatCurry programs.

The first is that every primitive value, a literal value of type \textit{Int}, \textit{Float}, or \textit{Char} is replaced with a constructor of the appropriate type. For example \(5 + 6\) is transformed into the expression \((\textit{Int} \ 5) + (\textit{Int} \ 6)\).

Second, we need to wrap cases of literal values with cases that remove the box. This can best be demonstrated with the example in Figure \[8.74\]. The value \(x\) is
evaluated down to an Int node, then we extract the unboxed integer \( x_{\text{prim}} \) and proceed with the primitive case statement. We also add one dummy branch to the unboxing case for each branch in the primitive case. These branches are there to instruct the code generator on what values a free variable could take on.

\[
\begin{align*}
\text{case } x \text{ of} \\
\text{case } x \text{ of} \\
0 \to \text{False} \\
1 \to \text{True}
\end{align*}
\]

\[
\begin{align*}
\text{Int } x_{\text{prim}} \to \text{case } x_{\text{prim}} \text{ of} \\
0 \to \text{False} \\
1 \to \text{True} \\
0 \to \text{free case} \\
1 \to \text{free case}
\end{align*}
\]

Figure 8.74: Wrapping a primitive case with a case to remove the box.

Finally we need to give new definitions for primitive operations such as + and \( \leq \). All of the operators fit the same pattern, so we only give the definitions for + and \( \leq \) for integers in Figure 8.75. In order to evaluate a + node, we evaluate the first argument to its box, then we unbox it with the case statement. We do not have any dummy branches for free variables. This represents the fact that + is a rigid operation. We proceed to evaluate and unbox the second argument. Finally, we return the result inside of a new box. The \( +_{\text{prim}} \) operation performs the addition, and is translated to an add expression in C. The \( \leq_{\text{prim}} \) operation performs a comparison between two integers, and returns either True or False based on the result.

Before we even look at trying to remove these boxes, it is worth taking a second to see if we can optimize literal values. There are actually a couple of significant improvements we can make that apply more broadly.
\((+) :: \text{Int} \rightarrow \text{Int} \rightarrow \text{Int}\)

\[ x + y = \text{case } x \text{ of} \]

\[ \text{Int } x_{\text{prim}} \rightarrow \text{case } y \text{ of} \]

\[ \text{Int } y_{\text{prim}} \rightarrow \text{let } v = x_{\text{prim}} +_{\text{prim}} y_{\text{prim}} \]

\[ \text{in } \text{Int } v \]

\((\leq) :: \text{Int} \rightarrow \text{Int} \rightarrow \text{Bool}\)

\[ x \leq y = \text{case } x \text{ of} \]

\[ \text{Int } x_{\text{prim}} \rightarrow \text{case } y \text{ of} \]

\[ \text{Int } y_{\text{prim}} \rightarrow x_{\text{prim}} \leq_{\text{prim}} y_{\text{prim}} \]

Figure 8.75: Definitions for + and ≤ taking boxed integers.

The first is that for any constructor with no arguments, such as True or Nothing, we can create a single static node to represent that constructor. This eliminates the need to allocate memory for each instance of True. While this is great, we might expect to go further. For example, if we could turn case statements of Boolean expressions into simple if statements in C. We could compare the scrutinee to True, and if it is, then we evaluate the true branch, otherwise we evaluate the false branch. Unfortunately, this does not work for two reasons. First, not all instances of True can be the static True nodes. As an example, at run-time not False will evaluate to True, but the node is going to be in the same location as the original not node. Second, even if we have a Boolean expression that has been evaluated to a value, it could still be a FAIL or FREE node.

The next optimization we can make is for the primitive types Int, Char, and Float. Since these constructors have an argument, namely the primitive value, we cannot make a single static node for them. We might try to create a single static
node for every literal value used in the program. Unfortunately this does not tend to help us that much. Consider the standard factorial program:

\[
\text{fac } n = \text{case } n \text{ of }
\begin{align*}
0 & \rightarrow 1 \\
n & \rightarrow n \ast \text{fac } (n - 1)
\end{align*}
\]

Now if we evaluate \(\text{fac } 42\), we will allocate memory up front for 0, 1, and 42. This will certainly save some memory, but not as much as we would hope. We will still construct every number between 2 and 41.

A better solution is to employ the flyweight pattern similar to the JVM. The idea is that small integers are likely to come up often. So, we statically allocate all of the integers between \(-128\) and \(128\). We do a similar allocation for characters. Unfortunately, this patterns did not show improved performance for floating point numbers.

Now that we have seen how to represent boxes, we can work on removing them, and see what we actually gain from it.

8.1.2 Unboxed Values

In order to get an idea of the effectiveness of unboxing, let us look at an example. Consider the function to compute Fibonacci numbers if Figure 8.76. We will work with this example extensively in the next couple of optimizations, in an attempt to see how much we can optimize it.

Unfortunately, using the optimizations we have already discussed, this function can not be optimized any further. The \(\text{fib}\) function is recursive, so we can not reduce it, and \(n - 1\) contains a primitive operation. However, we allocate a lot of memory while evaluating this function. We create 5 nodes for each recursive call, \(\text{cont}, n_1, f_1, n_2, f_2\). We do not create a node for \(f_1 + f_2\) since that will replace the root node during evaluation. We can statically allocate a node for each integer, because
\[ \text{fib} :: \text{Int} \rightarrow \text{Int} \]
\[ \text{fib} \; n = \text{case} \; n \leq 1 \; \text{of} \]
\[ \quad \text{True} \rightarrow n \]
\[ \quad \text{False} \rightarrow \text{fib} \; (n - 1) + \text{fib} \; (n - 2) \]

After translating to A-Normal Form:

\[ \text{fib} :: \text{Int} \rightarrow \text{Int} \]
\[ \text{fib} \; n = \text{let} \; \text{cond} = n \leq 1 \]
\[ \quad \text{in case} \; \text{cond} \; \text{of} \]
\[ \quad \text{True} \rightarrow n \]
\[ \quad \text{False} \rightarrow \text{let} \; n_1 = n - 1 \]
\[ \quad \quad \text{in let} \; f_1 = \text{fib} \; n_1 \]
\[ \quad \quad \text{in let} \; n_2 = n - 2 \]
\[ \quad \quad \text{in let} \; f_2 = \text{fib} \; n_2 \; \text{in} \; f_1 + f_2 \]

After adding boxes:

\[ \text{fib} :: \text{Int} \rightarrow \text{Int} \]
\[ \text{fib} \; n = \text{let} \; \text{cond} = n \leq \text{Int} \; 1 \]
\[ \quad \text{in case} \; \text{cond} \; \text{of} \]
\[ \quad \text{True} \rightarrow n \]
\[ \quad \text{False} \rightarrow \text{let} \; n_1 = n - \text{Int} \; 1 \]
\[ \quad \quad \text{in let} \; f_1 = \text{fib} \; n_1 \]
\[ \quad \quad \text{in let} \; n_2 = n - \text{Int} \; 2 \]
\[ \quad \quad \text{in let} \; f_2 = \text{fib} \; n_2 \; \text{in} \; f_1 + f_2 \]

Figure 8.76: A program for generating Fibonacci numbers translated to ANF, and adding boxes.
the integers are constant. However, there is still no need for this much allocation. The problem is that each of our primitive operations and recursive calls must be represented as a node to fit in with our definition of an expression graph.

However, after explicitly representing the boxes, and using our new definitions for + and \(\leq\), we can optimize \(fib\) to the program given in Figure 8.77.

\[
\begin{align*}
  fib \ n &= \ \textbf{case} \ n \ \textbf{of} \\
  \text{Int} \ v_2 \rightarrow \ \textbf{let} \ \textit{cond} = v_2 \ \leq_{\text{prim}} 1 \\
  \quad \textbf{in} \ \textbf{case} \ \textit{cond} \\
  \quad \quad \text{True} \rightarrow n \\
  \quad \quad \text{False} \rightarrow \ \textbf{let} \ n_1 = v_2 \ -_{\text{prim}} 1 \\
  \quad \quad \quad \textbf{in} \ \textbf{let} \ f_1 = fib (\text{Int} \ n_1) \\
  \quad \quad \quad \textbf{in} \ \textbf{case} \ f_1 \ \textbf{of} \\
  \quad \quad \quad \quad \text{Int} \ p_1 \rightarrow \ \textbf{let} \ n_2 = v_2 \ -_{\text{prim}} 2 \\
  \quad \quad \quad \quad \quad \textbf{in} \ \textbf{let} \ f_2 = fib (\text{Int} \ n_2) \\
  \quad \quad \quad \quad \quad \textbf{in} \ \textbf{case} \ f_2 \ \textbf{of} \\
  \quad \quad \quad \quad \quad \quad \text{Int} \ p_2 \rightarrow \ \textbf{let} \ r = p_1 \ +_{\text{prim}} p_2 \\
  \quad \quad \quad \quad \quad \quad \quad \textbf{in} \ \text{Int} \ r
\end{align*}
\]

Figure 8.77: Optimized \(fib\) after Unboxing

As we can see, the code is significantly longer, but now we have included the primitive operations in our code. The variables \(v_2, n_1, n_2, p_1, p_2\) are all primitive values, so we do not need to allocate any memory for them, so they will not be represented as nodes in our expression graph. This seems like a big win, but it is a little deceptive. We are still allocating 1 node for \(\textit{cond}, f_1, f_2\) and 2 nodes for the \textit{Int} constructors. So, we are still allocating 5 nodes, which is just as much memory
as before. This is an improvement in efficiency, but we can certainly do better.

8.1.3 Primitive Conditions

The first optimization is that we really do not need to allocate memory for \( \text{cond} \). \( x \leq_{\text{prim}} y \) should compile down to an expression involving the primitive \( \leq \) operation in C, and return a Boolean value. However, right now there is no way to signal that to the code generator, so we introduce the \texttt{pcase} construct.

The \( \text{primCond} \) must be a primitive condition expression, which is either \( =_{\text{prim}} \) or \( \leq_{\text{prim}} \), and the arguments must be primitive values. Perhaps surprisingly, these are the only primitive relational operators in Curry. All other relations operators are converted to combinations of \( =_{\text{prim}}, \leq_{\text{prim}}, \) and \( \text{not} \). The semantics of \texttt{pcase} are exactly what be expected, but now we can translate it into a simple \texttt{if} statement in C, as shown in Figure 8.78.

This has several advantages. First we do not construct a node for the Boolean value. Even if we are statically allocating a single node value for \( \text{True} \) and \( \text{False} \), we avoid the cost of switch case loop, and the cost of checking if \( \text{primcond} \) is non-deterministic. It must be deterministic, because both of its operands are primitive values. After implementing this construct, the new version is in Figure 8.79. Now we are down to 4 nodes, but we can still do better. The next challenge is unboxing the arguments in the call to \( \text{fib} \).

8.1.4 Strictness Analysis

The problems with eliminating boxes from arguments of function calls is strongly related to the run-time system and how we represent nodes in our expression graph. Recall that our expression graph is made up of node structs that point to other node structs. If we have a \( \text{fib} \) node, then the argument to this node is expected to be another node. In C we can get around this by using a union. We created a union \texttt{field}, defined in Figure 8.80 that can either represent an \texttt{Int}, \texttt{Char}, \texttt{Float},
\textbf{pcase} \textit{primCond} of
\begin{align*}
\text{True} & \rightarrow e_t \\
\text{False} & \rightarrow e_f
\end{align*}

\textit{B(pcase primCond of \{ True \rightarrow e_t; False \rightarrow e_f \})} := \\
\begin{align*}
\text{if}(\mathcal{E}_M(\text{primCond})) \\
\{ \\
\quad B(e_t) \\
\} \\
\text{else} \\
\{ \\
\quad B(e_f) \\
\}
\end{align*}

Figure 8.78: The \textbf{pcase} Construct
\[
\text{fib } n = \text{ case } n \text{ of } \\
\text{Int } v_2 \rightarrow \text{pcase } v_2 \leq_{\text{prim}} 1 \\
\text{True} \rightarrow n \\
\text{False} \rightarrow \text{let } n_1 = v_2 -_{\text{prim}} 1 \\
\hspace{1cm} \text{in let } f_1 = \text{fib (Int } n_1) \\
\hspace{1cm} \text{in case } f_1 \text{ of } \\
\hspace{2cm} \text{Int } p_1 \rightarrow \text{let } n_2 = v_2 -_{\text{prim}} 2 \\
\hspace{3cm} \text{in let } f_2 = \text{fib (Int } n_2) \\
\hspace{3cm} \text{in case } f_2 \text{ of } \\
\hspace{4cm} \text{Int } p_2 \rightarrow \text{let } r = p_1 +_{\text{prim}} p_2 \\
\hspace{5cm} \text{in } \text{Int } r
\]

Figure 8.79: The \text{fib} function with primitive cases.
Node, or an array of Node* in case a node has more than 3 children.

```c
typedef union field
{
    struct Node* n; //normal node child
    union field* a; //array child
    unsigned long c; //primitive character
    long i; //primitive int
    double f; //primitive float
}
field;
```

Figure 8.80: Definition of field Type.

The problem with storing a primitive value in a node, instead moves to identifying when a value is primitive. There is no way to distinguish between Node* and unsigned long. Instead of trying to figure out when a child of a node is supposed to represent a primitive value at run-time. We need to keep track of this information at compile time. Fortunately, this is a well studied problem [72, 82, 93].

Lazy functional languages often try to remove laziness for efficiency reasons. We do not want to create an expression for a primitive value if we are only going to deconstruct it, so it becomes useful to know what parameters in a function must be evaluated, A parameter that must be evaluated by a function is called strict. Formally, a function \(f\) is strict in its parameter if \(f \bot = \bot\).

We use \(\bot\) here to mean that the value of its parameter does not evaluate to a value, this can come from a call to the error function, or an infinite computation. It does not mean that \(f\) failed to return a value. We explicitly exclude that case, because that can change the results of some Curry programs. For example consider the function:
\( f \ x = head \ [\] \)

If we were to mark \( x \) as strict, then we may try to evaluate \( x \) before computing \( f \). This could cause an infinite loop in the following program:

\[
\begin{align*}
\text{loop} &= \text{loop} \\
\text{main} &= (f \ \text{loop}) \ ? \ 1
\end{align*}
\]

This should return a single result, and never try to evaluate \( \text{loop} \). For this reason we consider failing computations to be similar to expressions rooted by constructors for the purposes of strictness analysis.

We implemented an earlier form of strictness analysis described by Peyton Jones et al. [65]. This is a very limited form of abstract interpretation. The idea is that we start by assuming every function is strict in all its parameters. Then as we analyze a function we determine which parameters can be relaxed. For example consider the following function:

\[
f \ x \ y \ z = \text{case} \ x \ \text{of} \\
\quad \text{True} \rightarrow y \\
\quad \text{False} \rightarrow y + z
\]

It is clear that \( x \) must be strict, but we do not know about \( y \) or \( z \). After analyzing the case branches, we see that since \( y \) appears in both branches, and \(+\) is strict in both of its arguments, \( y \) must be strict as well. Finally, since there is a branch that \( z \) does not appear in, \( z \) may not be evaluated, so it is not strict.

This syntactic traversal of an expression is useful, but it fails when working with a recursively defined function. Consider the factorial function with an accumulator:

\[
faca \ n \ acc = \text{case} \ n=\text{=}0 \ \text{of} \\
\quad \text{True} \rightarrow acc \\
\quad \text{False} \rightarrow n \ * \ faca \ (n - 1) \ (n \ * \ acc)
\]
We can see with a syntactic check that \( n \) is strict, but what about \( acc \). \( acc \) does appear in both branches, but it is the argument to the recursive call of \( faca \). Therefore we have \( acc \), the second parameter of \( faca \), is strict if, and only if, the second parameter of \( faca \) is strict. We can solve this problem by iteratively running the strictness analyzer on \( faca \) until it converges to a single set of strict parameters. Formally, since a variable can be either strict or not strict, we can represent it with a 2 element set \( \{0, 1\} \), and our strictness analyzer is a monotonic function, so we are computing a least fixed point in the strictness analyzer over the set \( 2^n \) where \( n \) is the arity of the function.

There are much more sophisticated implementations of strictness analysis. We do not analyze deeper than a single pattern, and we are very conservative in regard to recursive functions. Mycroft’s original work was to interpret functions as Boolean formulas \([82]\). This can find several cases of strict parameters that our implementation does not. There has also been a lot of work on projection based strictness analysis \([72]\). The current state of the art for Haskell is backwards projection analysis \([93]\). Studying the validity and implementation of these strictness analyzers in regard to Curry would all be great candidates for future work.

Once we know which arguments are strict we can split the function into a wrapper function and a worker function \([93]\). We can see this with \( fib \). We take the current optimized version in Figure 8.79 and apply the worker/wrapper split in Figure 8.81. This creates two functions, \( fib \), which simply evaluates and unboxes the parameter, \( fib\#worker \), which does the rest of the computation. Then we optimize the function again resulting in Figure 8.82. Notice that since \( fib \) is no longer recursive we can inline it.
We can inline the call to \texttt{fib} in the following code:

\begin{verbatim}
let \( f_1 = \text{fib} (\text{Int} \; n_1) \)
\end{verbatim}

This results in:

\begin{verbatim}
let \( f_1 = \text{case} \; (\text{Int} \; n_1) \; \text{of} \\
\quad \text{Int} \; v_2 \rightarrow \text{fib}\#\text{worker} \; v_2 \)
\end{verbatim}

Which can be optimized to:

\begin{verbatim}
let \( f_1 = \text{fib}\#\text{worker} \; n_1 \)
\end{verbatim}

We are down to allocating 2 nodes. We only need to allocate nodes for the calls to \texttt{fib\#worker}. This means that we have reduced our memory consumption by 60%. That is a huge improvement, but we can still do better. With the next optimization we look at how to remove the remaining allocations.

\section*{8.2 CASE SHORTCUTTING}

In the last section we were able to optimize the \texttt{fib} function from allocating 5 nodes per recursive call to only allocating 2 nodes per recursive call. However, we were left with a problem that we can not solve by a code transformation.

\begin{verbatim}
let \( f_1 = \text{fib}\#\text{worker} \; n_1 \\
\text{in case} \; f_1 \; \text{of} \\
\quad \text{Int} \; p_1 \rightarrow \ldots 
\end{verbatim}

In this section we aim to eliminate these final two nodes. However, in order to do this, we will have to step outside of compile-time optimizations, and look into previous work on run-time optimizations for Curry. Specifically we are going to use an idea inspired by the shortcutting optimizations [18]. However, shortcutting
\[
\text{fib } n = \text{case } n \text{ of } \\
\hspace{1cm} \text{Int } v_2 \rightarrow \text{fib#worker } v_2 \\
\text{fib#worker } v_1 = \\
\hspace{1cm} \text{let } n = \text{Int } v_1 \\
\hspace{1cm} \text{in case } n \text{ of } \\
\hspace{2cm} \text{Int } v_2 \rightarrow \text{pcase } v_2 \preceq_{\text{prim}} 1 \text{ of } \\
\hspace{3cm} \text{True } \rightarrow n \\
\hspace{3cm} \text{False } \rightarrow \text{let } n_1 = v_2 -_{\text{prim}} 1 \\
\hspace{4cm} \text{in let } f_1 = \text{fib} (\text{Int } n_1) \\
\hspace{4cm} \text{in case } f_1 \text{ of } \\
\hspace{5cm} \text{Int } p_1 \rightarrow \text{let } n_2 = v_2 -_{\text{prim}} 2 \\
\hspace{6cm} \text{in let } f_2 = \text{fib} (\text{Int } n_2) \\
\hspace{6cm} \text{in case } f_2 \text{ of } \\
\hspace{7cm} \text{Int } p_2 \rightarrow \text{let } r = p_1 +_{\text{prim}} p_2 \\
\hspace{8cm} \text{in Int } r 
\]
\[
\text{fib}\#\text{worker } v_2 = \\
\text{pcase } v_2 \leq_{\text{prim}} 1 \text{ of} \\
\quad \text{True } \rightarrow \text{Int } v_2 \\
\quad \text{False } \rightarrow \text{let } n_1 = v_2 -_{\text{prim}} 1 \\
\quad \quad \text{in let } f_1 = \text{fib}\#\text{worker } n_1 \\
\quad \quad \text{in case } f_1 \text{ of} \\
\quad \quad \quad \text{Int } p_1 \rightarrow \text{let } n_2 = v_2 -_{\text{prim}} 2 \\
\quad \quad \quad \quad \text{in let } f_2 = \text{fib}\#\text{worker } n_2 \\
\quad \quad \quad \text{in case } f_2 \text{ of} \\
\quad \quad \quad \quad \quad \text{Int } p_2 \rightarrow \text{let } r = p_1 +_{\text{prim}} p_2 \\
\quad \quad \quad \quad \quad \quad \text{in Int } r
\]

Figure 8.82: The \text{fib} function after strictness analysis and optimization.
was designed for rewrite systems, and the idea doesn’t quite match how our run-
time evaluates expressions. However the goal of shortcutting was to eliminate the
construction of nodes using a systematic transformation of the rewriting system.
In this spirit, we have transformed the generated code to eliminate nodes that are
constructed, only to be quickly evaluated and deconstructed by case statements.
This “case shortcutting” has proven to be very effective in eliminating many mem-
ory allocations.

We will often find examples of expressions that are constructed, and immedi-
ately evaluated by a case statement, after which, the results are never used again.
Both $f_1$ and $f_2$ in Figure 8.82 are excellent examples of such expressions. Typi-
cally a compiler for a lazy language would recognize this situation, and instead of
generating a node only to evaluate it, the compiler would produce a function call
that would return the value of that node.

It is worth looking at an attempt to try to replace the node with a function call.
One possibility would be to try to statically analyze a function $f$ and determine
if it is deterministic. This is a reasonable idea, but it has two major drawbacks.
First, determining if a function is non-deterministic is undecidable, so the best we
could do is an approximation. Second, even if $f$ is deterministic, the expression
$f \, x$ could still be non-deterministic if $x$ is. This is going to be very restrictive for
any possible optimization.

In the example in Figure 8.82 we need a node to hold the value for $\text{fib\#worker} \, n_1$,
but this value will only be used in the case expression. In fact, it is not possible for
this node to be shared with any part of the expression graph. If this expression is
only ever scrutinized by the case expression, then we only need to keep the value
around temporarily. The idea here is simple, but the implementation becomes
tricky. We want to use a single, statically allocated, node for every variable that
is only used as the scrutinee of a case.

There are two steps to the optimization. The first step is marking every node
that is only used as the scrutinee. The second step happens during code generation. Instead of dynamically allocating memory for a marked node, we store all of the information in a single, statically allocated, node. We call this node RET for return.

This effectively removes the rest of the dynamically allocated nodes from our fib function, but before we celebrate, we need to make sure that code generated using this transformation actually produces the same results. There are a few things that can potentially go wrong.

First, let us look at the case where the scrutinee is deterministic. In that case, there is only one thing that could go wrong. It is possible that in order to reduce the scrutinee we need to reduce another expression that could be stored in RET. For example, consider the following program:

\[
\begin{align*}
  f \ x & = \text{case } g \ x \ of \\
  & \quad \text{True } \rightarrow \text{False} \\
  & \quad \text{False } \rightarrow \text{True}
\end{align*}
\]

\[
\begin{align*}
  \text{main} & = \text{case } f \ 3 \ of \\
  & \quad \text{True } \rightarrow \text{0} \\
  & \quad \text{False } \rightarrow \text{1}
\end{align*}
\]

In the evaluation of main, f 3 can be stored in the RET node, then we can evaluate f 3 to head constructor form, but while we are evaluating f 3, we store g 3 in the same RET node. While this is concerning, it is not actually a problem. As shown in Chapter 3.2.7 at the beginning of f.hnf, we store all of the children of root as local variables, and then when we have computed the value, we overwrite the root node. In our case the root node in our function is RET. However, aside from the very start and end of the function, we never interact with the root node, so even if we reuse RET in the middle of evaluating f, it does not actually affect the results.

A portion of the generated code for f can be seen in Figure 8.83. As we can
see, the only time that we use the root node is at the very start of the function to store the variables, and right before we return. Even if root happens to be RET, this does not actually affect the evaluation. The RET node is overwritten with the contents of g x, then it is evaluated, and finally it is overwritten with the result of f right before returning.

```c
void f_hnf(Node* root)
{
    field x = root->children[0];
    set_g(RET, make_int(3));
    field scrutinee = RET;
    bool nondet = false;
    while(true)
    {
        nondet |= scrutinee.n->nondet;
        switch(TAG(scrutinee))
        {
            ... 
            case True:
                if(nondet) push_frame(root, make_Prelude_f_1(x));
                set_Prelude_False(root, 0);
                return;
        }
    }
}
```

Figure 8.83: Generated Code with RET Nodes
It seems like we should be able to store these marked variables in the \texttt{RET} node, and then just call the appropriate \texttt{hnf} function. In fact this was the first idea we tried. The generated code for main is given in Figure 8.84.

```c
void main_hnf(Node* root)
{
    set_f(RET, make_int(3));
    field scrutinee = RET;
    bool nondet = false;
    while(true)
    {
        nondet |= scrutinee.n->nondet;
        switch(TAG(scrutinee))
        {
          ...
          case True:
              if(nondet) ...
              set_int(root, 0);
              return;
          ...
        }
    }
}
```

Figure 8.84: main with Shortcutting First Attempt

This initial version actually works very well. In fact, for $fib\#worker$ we are able to remove the remaining 2 allocations. This is fantastic, and we will come back to this point later, but we need to deal with a looming problem.
8.2.1 Non-deterministic RET Nodes

The problem with the scheme we have developed so far is that if RET is non-deterministic, then the rewrite rule we push on the backtracking stack may contain a pointer to RET. This is a major problem with this optimization, because RET will almost certainly have been reused by the time backtracking occurs.

This optimization was built on the idea that RET is only ever used in a single case expression. Therefore, it is important that we never put RET on the backtracking stack. We need rethink on our idea. Initially, we wanted to avoid allocating a node if a variable is used in a single case. Instead, we will only allocate a node if RET is non-deterministic. This means that for deterministic expression, we do not allocate any memory, but for non-deterministic expression, we still have a persistent variable on the stack. This lead to the second implementation in Figure 8.85.

8.2.2 RET hnf Functions

In the last section we copied RET nodes before pushing them onto the backtracking stack, this is an improvement on our first approach, because the backtracking stack does not include any RET nodes, but it’s still not quite correct. Three things can still go wrong here. These are very subtle errors that are very easy to overlook, and even harder to track down the real cause of the errors.

The first problem is that RET might have been reduced to a forwarding node, so it might be deterministic, but forward to a non-deterministic node. For example, in case id (0 ? 1) of ... there is clearly non-determinism, but the id node is not the cause of it, so that rewrite should not be pushed on the backtracking stack.

Another problem is that, if RET is a forwarding node, when evaluating the node it forwards to, we might have reused RET. Consider the following program:
void main_hnf(Node* root)
{
    set_f(RET, make_int(3));
    field scrutinee = RET;
    bool nondet = false;
    while(true)
    {
        nondet |= scrutinee.n->nondet;
        switch(scrutinee.n->tag)
        {
            ... 
            case True:
                if(nondet)
                {
                    Node* backup = copy(RET);
                    stack_push(bt_stack, root, main_1(backup));
                }
                set_int(root, 0);
                return;
        ... 
    }
}

Figure 8.85: main with Shortcutting Second Attempt
\[ h \ x = \text{case } x > 3 \text{ of} \]
\[ \quad \text{False} \rightarrow 3 \]
\[ \quad \text{True} \rightarrow 4 \]

\[ \text{main} = \text{case } (h \ 4 ? h \ 2) \text{ of} \]
\[ \quad 4 \rightarrow \text{True} \]

Here \( \text{main} \) evaluates \( h \ 4 ? h \ 2 \). Since \( ? \) is non-deterministic, and reduces to a forwarding node, we need to make a copy of \( \text{RET} \) as part of the rewrite we push on the backtracking stack. However, before we can even do that, we need to evaluate \( h \ 4 \), and the expression \( x > 3 \) will be stored in \( \text{RET} \). Now we have lost the information in \( \text{RET} \) before we can copy it. Finally, we still have not avoided putting \( \text{RET} \) on the backtracking stack. Recall our program from before:

\[ f \ x = \text{case } g \ x \text{ of} \]
\[ \quad \text{True} \rightarrow \text{False} \]
\[ \quad \text{False} \rightarrow \text{True} \]

\[ \text{main} = \text{case } f \ 3 \text{ of} \]
\[ \quad \text{True} \rightarrow 0 \]
\[ \quad \text{False} \rightarrow 1 \]

If the expression \( g \ x \) is non-deterministic, then the node containing \( f \) will be marked as non-deterministic. However, \( f \ 3 \) was stored in the \( \text{RET} \) node, so the \texttt{root} parameter will be \( \text{RET} \). Now \( \text{RET} \) is still pushed on the backtracking stack, but this time it is on the left hand side of the rewrite.

This is starting to seem hopeless, when we fix one problem, 3 much more subtle problems pop up. How can we avoid creating nodes for deterministic expressions, but still only create a single node that the caller and callee agree on if the expression is non-deterministic?

The answer is that we need to change how \( \text{RET} \) nodes are reduced. Specifically,
we create a new reduction function that only handles nodes stored in \texttt{RET}. In the case of \( f \), we would create a \texttt{f.hnf}, a \texttt{f.1.hnf} and a \texttt{f.RET.hnf}. The third function only reduces \( f \) that has been stored in a \texttt{RET} node.

The difference between \texttt{f.hnf} and \texttt{f.RET.hnf} is that instead of passing the root node, we pass \texttt{Node* backup}. The \texttt{backup} node is where we will store the contents of \texttt{RET} if we discover evaluating the expression rooted by \( f \) is non-deterministic. Finally we return \texttt{backup}. Now both the caller and callee agree on \texttt{backup}. Furthermore, since \texttt{backup} is a local variable, it is not affected if \( f \) reuses \texttt{RET} over the course of its evaluation. We can see the final implementation of shortcutting for \texttt{main} in Figure 8.86. We also give the definition for \texttt{f.RET.hnf} in Figure 8.87.

Now, we finally have a working function. We only allocate memory if the scrutinee of the case is non-deterministic. If the expression is non-deterministic in multiple places, then the same \texttt{backup} node is pushed on the stack, so our expression graphs stay consistent. This also works well if we have multiple reductions in a row. Suppose we have the following Curry code:

\begin{verbatim}
main = case f 4 of
        True \rightarrow False
        False \rightarrow False

f n = case n of
        0 \rightarrow True
        _ \rightarrow f (n - 1)
\end{verbatim}

In this case \( f \) is a recursive function, so when we reduce \( f\ 4 \), we need to reduce \( f\ 3 \). This is no problem at all, because we are reducing \( f\ 4 \) with \texttt{f.RET.hnf}. Ignoring the complications of Unboxing for the moment, we can generate the following code for the return of \( f \).
void main_hnf(Node* root) {
    set_f(RET, make_int(3));
    field scrutinee = RET;
    Node* f_backup = f_RET_hnf(NULL);
    bool nondet = false;
    if(f_backup != NULL) {
        nondet = true;
        memcpy(f_backup, RET.n, sizeof(Node));
    } else if(RET.n->tag == FORWARD_TAG) {
        f_backup = RET.n->children[0];
    }
    while(true) {
        nondet |= scrutinee.n->nondet;
        switch(scrutinee.n->tag) {
            ...
            case True:
                if(nondet)
                {
                    stack_push(bt_stack, root, main_1(f_backup));
                }
                set_int(root, 0);
                return;
                ...
        } }

Figure 8.86: main with Shortcutting
Node* f_RET_hnf(Node* backup) {
    Node* v1 = RET->children[0];
    set_g(RET, v1);
    field scrutinee = RET;
    Node* g_backup = g_RET_hnf(NULL);
    bool nondet = false;
    if(g_backup != NULL) {
        nondet = true;
        memcpy(g_backup, RET.n, sizeof(Node));
    } else if(RET.n->tag == FOR ward_TAG)
        g_backup = RET.n->children[0];
    while(true) {
        nondet |= scrutinee.n->nondet;
        switch(RET_forward->tag) {
            ... 
        }
        case True:
            if(nondet) {
                if(!backup)
                    backup = (Node*)malloc(sizeof(Node));
                set_False(backup);
                stack_push(bt_stack, backup, g_backup);
            }
            set_False(RET);
            return backup;
            ... } }

Figure 8.87: Compiling f with Shortcutting
field v2 = make_int(n-1)
set_f(RET, v2);
return f_RET_hnf(backup);

8.2.3 Shortcutting Results

Before we move onto our next optimization, we should look back at what we have done so far. Initially, we had a \texttt{fib} function that allocated 5 nodes for every recursive call. Then, through Unboxing, we were able to cut that down to only 2 allocations per call. Finally, using Shortcutting, we were able to eliminate those two allocations. We would expect a substantial speedup by reducing memory consumption by 60%, but removing those last two allocations is a difference in kind. The \texttt{fib} function runs in exponential time, and since each step allocates some memory, the original \texttt{fib} function allocated an exponential amount of memory on the heap. However, our fully optimized \texttt{fib} function only allocates a static node at startup. We have moved from exponential memory allocated on the heap to constant space. While \texttt{fib} still runs in exponential time, it runs much faster, since it does not need to allocate memory. Surprisingly, \texttt{fib} is still just as efficient with non-deterministic arguments. If the argument is non-deterministic, the wrapper function will evaluate it before calling the worker.

Now that we have removed most of the implicitly allocated memory with Unboxing and Shortcutting, we can work on removing explicitly allocated memory with a technique from functional languages.

8.3 DEFORESTATION

We now turn to our final optimization, Deforestation. The goal of this optimization is to remove intermediate data structures. Programmers often write in a pipeline style when writing functional programs. For example, consider the program:
\[ \text{sumPrimes} = \text{sum} \circ \text{filter isPrime} \circ \text{enumFromTo} \ 2 \]

While this style is concise and readable, it is not efficient. First, we create a list of integers, then we create a new list of all of the integers in our list that are prime, and finally we sum the values in that list. It would be much more efficient to compute this sum directly.

\[ \text{sumPrimes} \ n = \text{go} \ 2 \ n \]

where \( \text{go} \ k \ n \) 
- \( k \geq n = 0 \)
- \( \text{isPrime} \ k = k + \text{go} \ (k + 1) \ n \)
- otherwise = \( \text{go} \ (k + 1) \ n \)

This pipeline pattern is pervasive in functional programming, so it is worth understanding and optimizing it. In particular, we want to eliminate the two intermediate lists created here. This is the goal of Deforestation.

8.3.1 The Original Scheme

Deforestation has actually gone through several forms throughout its history. The original optimization proposed by Wadler [100] was very general, but it required a complicated algorithm, and it could fail to terminate. There have been various attempts to improve this algorithm [98] and [40] that have focused on restricting the form of programs.

An alternative was proposed by Gill in his dissertation [46,47] called foldr-build Deforestation or short-cut Deforestation. This approach is much simpler, always terminates, and has a nice correctness proof, but it comes at the cost of generality. Foldr-build Deforestation only works with functions that produce and consume lists. Still, lists are common enough in functional languages that this optimization has proven to be effective.

Since then foldr-build Deforestation has been extended to Stream Fusion [33].
While this optimization is able to cover more cases than foldr-build Deforestation, it relies on more advanced compiler technology.

The foldr-build optimization itself is actually very simple. It relies on an observation about the structure of a list. All lists in Curry are built up from cons and nil cells. The list \([1, 2, 3, 4]\) is really \(1 : 2 : 3 : 4 : \text{[]}\). One very common list processing technique is a fold, which takes a binary operation and a starting element, and reduces a list to a single value. In Curry, the \texttt{foldr} function is defined as:

\[
\text{foldr} :: (a \rightarrow b \rightarrow b) \rightarrow b \rightarrow [a] \rightarrow b
\]

\[
\text{foldr} \odot z [\text{}] = z
\]

\[
\text{foldr} \odot z (x : xs) = x \odot \text{foldr } f z xs
\]

As an example, we can define the \texttt{sum} function as \(\text{sum } xs = \text{foldr } (+) 0\). To see what this is really doing we can unroll the recursion. Suppose we evaluate \(\text{foldr } (+) 0 [1, 2, 3, 4, 5]\), then we have:

\[
\text{foldr } (+) 0 [1, 2, 3, 4, 5] \\
\Rightarrow 1 + \text{foldr } (+) 0 [2, 3, 4, 5] \\
\Rightarrow 1 + (2 + \text{foldr } (+) 0 [3, 4, 5]) \\
\Rightarrow 1 + (2 + (3 + \text{foldr } (+) 0 [4, 5])) \\
\Rightarrow 1 + (2 + (3 + (4 + \text{foldr } (+) 0 [5]))) \\
\Rightarrow 1 + (2 + (3 + (4 + (5 + \text{foldr } (+) 0 [\text{}])))) \\
\Rightarrow 1 + (2 + (3 + (4 + (5 + 0))))
\]

But wait, this looks very similar to our construction of a list.

\[
1 : (2 : (3 : (4 : (5 : (\text{}))))) \\
1 + (2 + (3 + (4 + (5 + 0))))
\]

We have just replaced the \(:\) with \(+\) and the \([\text{}]\) with \(0\). If the compiler can find where we will do this replacement, then we do not need to construct the list. On its own, this is a very hard problem, but we can help the compiler along. We
just need a standard way to construct a list. This can be done with the \textit{build} function [46].

\begin{equation}
\text{build} :: (\forall b (a \rightarrow b \rightarrow b) \rightarrow b \rightarrow b) \rightarrow [a] \\
\text{build} \ g = g (:)[]
\end{equation}

The \textit{build} function takes a function that constructs a list. However, instead of construction the list with : and [], we abstract this by passing the constructors in as arguments, which we call \textit{c} and \textit{n} respectively. Now, with \textit{build}, we can define what we mean by deforestation with a simple theorem from [46].

\textbf{Theorem 9.} For all \( f : a \rightarrow b \rightarrow b, z : b, \) and \( g : (\forall b (a \rightarrow b \rightarrow b) \rightarrow b \rightarrow b) \rightarrow [a], \)

\begin{equation}
\text{foldr} \ f \ z \ (\text{build} \ g) = g \ f \ z
\end{equation}

So, if we can construct standard list functions using \textit{build} and \textit{foldr}, then we can remove these function using the above theorem. As an example, let us look at the function \textit{enumFromTo} \( a \ b \) that constructs a list of integers from \( a \) to \( b \).

\begin{equation}
\text{enumFromTo} \ a \ b \\
| a > b = [] \\
| \text{otherwise} = a : \text{enumFromTo} \ (a + 1) \ b
\end{equation}

We can turn this into a build function.

\begin{equation}
\text{enumFromTo} \ a \ b = \text{build} \ (\text{enumFromTo} \_\text{build} \ a \ b) \\
\text{enumFromTo} \_\text{build} \ a \ b \ c \ n \\
| a > b = n \\
| \text{otherwise} = a \ c \ \text{enumFromTo} \_\text{build} \ (a + 1) \ b \ c \ n
\end{equation}

We can create build functions for several list creation functions found in the standard library. In fact, for this optimization we replace several functions in both the Prelude and List library with equivalent functions constructed with \textit{foldr}
and \textit{build}. Now we are ready to apply Deforestation to Curry. Unfortunately there are two problems we need to solve. The first is an implementation problem, and the second is a theoretical problem. First, while we can apply foldr/build Deforestation, we can not actually optimize the results. Second, we still need to show it is valid for curry.

\subsection*{8.3.2 The Combinator Problem}

Let us look back at the motivating example, and see how it could be optimized in Haskell, or any language that can inline lambda expressions. The derivation in Figure \ref{fig:filter} comes from the original paper \cite{46}.

This looks good. In fact, we obtained the original expression we were trying for. Unfortunately we do not get the same optimization in Rice. The problem is actually the definition of \textit{filter}.

\begin{equation*}
\text{filter } f = \text{build } (\lambda c \ n \to \text{foldr } (\lambda x \ y \to \text{if } f x \text{ then } x \ c \ y \ \text{else } y) \ n)
\end{equation*}

Functions that transform lists, such as \textit{filter}, \textit{map}, and \textit{concat}, are rewritten in the standard library as a build applied to a fold. Unfortunately our inliner can not produce this derivation. We do not inline lambda expressions, and reductions can only be applied to let bound variables, so we simply can not do this reduction. Instead we need a new solution.

\subsection*{8.3.3 Solution build\_fold}

Our solution to this problem is to introduce a new combinator for transforming lists. We call this \textit{build\_fold} since it is a build applied to a fold.

\begin{equation*}
\textbf{build\_fold} :: ((c \to b \to b) \to (a \to b \to b)) \to (b \to b) \to [a] \to b
\end{equation*}

\begin{equation*}
\text{build\_fold } mkf \ mkz \ xs = \text{foldr } (mkf (\cdot)) (mkz []) \ xs
\end{equation*}

The idea behind this combinator is a combination of a build and a fold. This
\[\text{sumPrimes } m = \text{sum } (\text{filter isPrime } (\text{enum } 2 m))\]

\[\Rightarrow\]

\[\text{sumPrimes } m = \text{foldr } (+) 0\]

\[\text{(build } \lambda n \rightarrow \text{foldr } (\lambda x y \rightarrow \text{if isPrime } x \text{ then } x \cdot c \cdot y \text{ else } y) n)\]

\[\Rightarrow\]

\[\text{sumPrimes } m = \text{foldr } (+) 0\]

\[\text{(build } \lambda n \rightarrow \text{enum } \text{build } 2 x (\lambda x y \rightarrow \text{if isPrime } x \text{ then } x \cdot c \cdot y \text{ else } y) n)\]

\[\Rightarrow\]

\[\text{sumPrimes } m = \text{enum } \text{build } 2 m (\lambda x y \rightarrow \text{if isPrime } x \text{ then } x + y \text{ else } y) 0\]

\[\Rightarrow\]

\[\text{sumPrimes } m = \text{enum } \text{build } 2 m (\lambda x y \rightarrow \text{if isPrime } x \text{ then } x + y \text{ else } y) 0\]

\[\text{where } \text{enum } \text{build } k m c z = \text{if } k > m \text{ then } z\]

\[\text{else } c k (\text{enum } \text{build } (k + 1) m c z)\]

\[\Rightarrow\]

\[\text{sumPrimes } m = \text{enum } \text{build } 2 m\]

\[\text{where } \text{enum } \text{build } k m = \text{if } k > m \text{ then } 0\]

\[\text{else } (\lambda x y \rightarrow \text{if isPrime } x \text{ then } x + y \text{ else } y) k (\text{enum } \text{build } (k + 1) m)\]

\[\Rightarrow\]

\[\text{sumPrimes } m = \text{enum } \text{build } 2 m\]

\[\text{where } \text{enum } \text{build } k m = \text{if } k > m \text{ then } 0 \text{ else if isPrime } k\]

\[\text{then } x + (\text{enum } \text{build } (k + 1) m c z)\]

\[\text{else } (\text{enum } \text{build } (k + 1) m)\]

Figure 8.88: Optimization derivation for short-cut Deforestation
function was designed to be easily composable with both build and fold. Ideally, it could fit in the middle of build and fold and still reduce. As an example:

```
foldr (+) 0 (build fold filter_mkf filter_mkz (build enumFromTo_build))
```

Ideally, this function should reduce into something relatively efficient, Furthermore we wanted `build_fold` to compose nicely with itself. For example, `map f \circ map g` should compose to something like `map (f \circ g)`.

We achieve this by combining pieces of both `build` and `foldr`. The two functions `mkf` and `mkz` make the `f` and `z` functions from fold, however they take `c` and `n` as arguments similar to `build`. The idea is that `mkf` takes an `f` from `foldr` as a parameter, and returns a new `f`. The `map` and `filter` implementations are given below.

```
map f = build_fold (map_mkf f) map_mkz
map_mkf f c x y = f x \cdot c \cdot y
map_mkz n = n

filter p = build_fold (filter_mkc p) filter_mkz
filter_mkf p c x y = if p x then x \cdot c \cdot y else y
filter_mkz n = n
```

The purpose of the convoluted definition of `build_fold` is that it plays nicely with `build` and `foldr`. We have the following three theorems about `build_fold`, which we will prove later. These are analogous to the `foldr / build` theorem.
Theorem 10. For all functions of the appropriate type that evaluate no \textit{?} expressions, the following qualities hold.

\[
\begin{align*}
\text{build} \text{fold } \text{mkf} \text{ mkz } (\text{build } g) &= \text{build} (\lambda c \ n \to g (\text{mkf } c) (\text{mkz } n)) \\
\text{foldr} \ f \ z \ (\text{build} \text{fold } \text{mkf} \text{ mkz } \text{xs}) &= \text{foldr} (\text{mkf } f) (\text{mkz } z) \text{xs} \\
\text{build} \text{fold } \text{mkf}_1 \text{ mkz}_1 \ (\text{build} \text{fold } \text{mkf}_2 \text{ mkz}_2 \text{xs}) \\
&= \text{build} \text{fold} (\text{mkf}_2 \circ \text{mkf}_1) (\text{mkz}_2 \circ \text{mkz}_1) \text{xs}
\end{align*}
\]

The proof of this theorem will be given in the next section. Now that we have removed all of the lambdas from our definitions, we can look at the implementation.

8.3.4 Implementation

Deforestation turned out to be one of the easiest optimizations to implement. The implementation is entirely in \texttt{GAS}, and it proceeds in two steps. First we find any case where a \texttt{build} or \texttt{build fold} occurs exactly once in either a \texttt{build fold} or \texttt{fold}. If this is the case, we inline the variable that \texttt{build} is bound to into it is single use. This temporarily takes our expression out of A-Normal Form, but we will restore that with the second step, which is the actual Deforestation transformation, which applies either the \texttt{foldr / build} theorem, or one of the three \texttt{build fold} theorems from above. The definitions for the deforest transformation are given in Figure 8.89. The optimization derivation for \textit{sumPrimes} is in Figures 8.90 and 8.91. The unused variables will be removed at a later time by dead code elimination.

So far we have done a decent job. It is not as efficient as the Haskell version, but that is not surprising. However, we can still improve this. The main problem here is that we can not optimize a partial application. This is unfortunate, because the \texttt{build fold} function tends to create large expressions of partially applied functions. Fortunately we have already solved this problem earlier in our compiler. We already have a way to detect if an expression is partially applied, so, in the post processing phase, we do a scan for any partially applied functions.
Inline foldr/build:

\[
\begin{align*}
\text{let } x &= \text{build } g \text{ in } e \quad \Rightarrow \quad e[\text{build } g \leftarrow [p, 2]] \\
| e|_p &= \text{foldr } x \\
\text{let } x &= \text{build } g \text{ in } e \quad \Rightarrow \quad e[\text{build } g \leftarrow [p, 2]] \\
| e|_p &= \text{build}_\text{fold } \_ \_ x \\
\text{let } x &= \text{build}_\text{fold } \text{mkf } \text{mkz in } e \quad \Rightarrow \quad e[\text{build}_\text{fold } \text{mkf } \text{mkz } \leftarrow [p, 2]] \\
| e|_p &= \text{foldr } f \ z \ x \\
\text{let } x &= \text{build}_\text{fold } \text{mkf } \text{mkz in } e \quad \Rightarrow \quad e[\text{build}_\text{fold } \text{mkf } \text{mkz } \leftarrow [p, 2]] \\
| e|_p &= \text{build}_\text{fold } \_ \_ x
\end{align*}
\]

Deforest foldr/build:

\[
\text{foldr } f \ z (\text{build } g) \quad \Rightarrow \quad g \ f \ z
\]

Deforest build/fold/build:

\[
\text{build}_\text{fold } \text{mkf } \text{mkz } (\text{build } g) \Rightarrow \text{build } (\lambda c \ n \to g (\text{mkf } c) (\text{mkz } n))
\]

Deforest foldr/build/build/fold:

\[
\text{foldr } f \ z (\text{build}_\text{fold } \text{mkf } \text{mkz } \text{xs}) \Rightarrow \text{let } f_1 = \text{mkf } f \text{ in let } z._1 = \text{mkz } z \text{ in foldr } f_1 \ z._1 \ \text{xs}
\]

Deforest build/fold/build/fold:

\[
\text{build}_\text{fold } \text{mkf}_1 \ \text{mkz}_1 \Rightarrow \text{let } f_1 = \text{mkf}_2 \circ \text{mkf}_1 \text{ in let } z._1 = \text{mkz}_2 \circ \text{mkz}_1 \text{ in build}_\text{fold } f_1 \ z._1 \ \text{xs}
\]

Figure 8.89: The Deforestation Optimization.

The lambda in the build rule is a call to a known function.
The lets are added to keep the expression in A-Normal Form.
The expression \( e \, | \, \text{cond} \Rightarrow e' \) should be read as “\( e \) rewrites to \( e' \) given that \( \text{cond} \) holds.”

Figure 8.91: Derivation of sumPrimes 2
If we find one, then we move the code into a newly created function, and attempt to optimize it. We call this function outlining, since it is the opposite of inlining. If we can not optimize the outlined function, then we do nothing. Otherwise, we make a new function, and replace the call to the partially applied function with a call to the outlined function. This would actually be worth doing even if we did not implement Deforestation. With function outlining our final optimized code is given below.

\[
\text{sumPrimes } n = \text{enumFromTo_
\text{build} 2 \ n f' 0
\]

\[
f' \ x \ y = \text{if isPrime } x \text{ then } x + y \text{ else } y
\]

\[
\text{enumFromTo_
\text{build} \ a \ b \ c \ n
\]

| a > b = n
| otherwise = a \ 'c' \ \text{enumFromTo_
\text{build} \ (a + 1) \ b \ c \ n
\]

This certainly is not perfect, but it is much closer to what we were hoping for. Combining this with Unboxing and Shortcutting gives us some very efficient code. While these results are very promising, we still need to know if Deforestation is even valid for Curry.

### 8.3.5 Correctness

First we show that the \text{build-fold} theorems are valid for a deterministic subset of Curry using the same reasoning as the original foldr-build rule. Without non-determinism and free variables, we can apply the same arguments as the original paper on shortcut deforestation [46].
Theorem 10. For any deterministic \( f, z, g, mkf \), and \( mkz \), the following equations hold.

\[
\begin{align*}
\text{build}_\text{fold} \ mkf \ mkz \ (\text{build} \ g) &= \text{build} \ (\lambda c \ n \to g \ (mkf \ c) \ (mkz \ n)) \\
\text{foldr} \ f \ z \ (\text{build}_\text{fold} \ mkf \ mkz \ xs) &= \text{foldr} \ (mkf \ f) \ (mkz \ z) \ xs \\
\text{build}_\text{fold} \ mkf_1 \ mkz_1 \ (\text{build}_\text{fold} \ mkf_2 \ mkz_2 \ xs) &= \text{build}_\text{fold} \ (mkf_2 \circ mkf_1) \ (mkz_2 \circ mkz_1) \ xs
\end{align*}
\]

Proof. Recall that the free theorem \[99\] for \text{build} is for all \( h, f, \) and \( f' \) of the appropriate type:

\[
\begin{align*}
(\forall \ (a : A) \ (\forall \ (b : B) \ h \ (f \ a \ b) = f' \ a \ (h \ b))) \Rightarrow \\
\forall \ (b : B) \ h \ (g_B \ f \ b) = g'_B \ f' \ (h \ b)
\end{align*}
\]

We substitute \text{build}_\text{fold} \ mkf \ mkz for \( h, (:) \) for \( f \) and \( mkf \ (:) \) for \( f' \). From the definition of \text{build}_\text{fold} we have \text{build}_\text{fold} \ mkf \ mkz \ (a:b) = (mkf \ (:)) \ a \ (\text{build}_\text{fold} \ mkf \ mkz \ b) \]
and \text{build}_\text{fold} \ mkf \ mkz \ [] = mkz \ [. Therefore we have \text{build}_\text{fold} \ mkf \ mkz \ (g \ (: \ b) = g \ (mkf \ (:)) \ (\text{build}_\text{fold} \ mkf \ mkz \ b)

This gives us the following result.

\[
\begin{align*}
\text{build}_\text{fold} \ mkf \ mkz \ (\text{build} \ g) &= g \ (mkf \ (:)) \ (mkz \ [])
\end{align*}
\]

Finally, working backwards from the definition of \text{build} we have our theorem.

\[
\begin{align*}
\text{build}_\text{fold} \ mkf \ mkz \ (\text{build} \ g) &= \text{build} \ (\lambda c \ n \to g \ (mkf \ c) \ (mkz \ n))
\end{align*}
\]

Again with \text{foldr} we have the free theorem

if \( \forall \ (a : A) \ (\forall \ (b : B) \ b \ (x \oplus y) = (a \ x) \otimes (b \ y) \) and \( b \ u = u' \)

then \( b \circ \text{foldr} \oplus u = \text{foldr} \otimes u' \circ (\text{map} \ a) \)

Here we take \( b = \text{build}_\text{fold} \ mkf \ mkz, \oplus = f, \) and \( \otimes = mkf \ f \ a = id \)

then the statement becomes:
if \(\text{build} \text{fold} \text{mk} f \text{mk}z (f \ x \ y) = (\text{mk}f \ f) \ x \ (\text{build} \text{fold} \text{mk} f \text{mk}z \ y)\)

and \(\text{build} \text{fold} \text{mk} f \text{mk}z [\ ] = \text{mk}z [\ ]\)

then \(\text{build} \text{fold} \text{mk} f \text{mk}z \circ \text{foldr} \ f \ z = \text{foldr} (\text{mk}f \ f) (\text{mk}z \ z)\)

Since both conditions follow directly from the definition of \(\text{build} \text{fold}\) we are left with

\[\text{build} \text{fold} \text{mk} f \text{mk}z \circ \text{foldr} \ f \ z = \text{foldr} (\text{mk}f \ f) (\text{mk}z \ z)\]

which is exactly what we wanted. Free theorems are fun!

Finally for \(\text{build} \text{fold} / \text{build} \text{fold}\) rule suppose we have the expression

\[\text{foldr} \ f \ z \ (\text{build} \text{fold} \text{mk}f_1 \text{mk}z_1 \ (\text{build} \text{fold} \text{mk}f_2 \text{mk}z_2 \ x))\]

From the previous result we have:

\[\text{foldr} \ (\text{mk}f_1 \ f) \ (\text{mk}z_1 \ z) \ (\text{build} \text{fold} \text{mk}f_2 \text{mk}z_2 \ x)\]
\[= \text{foldr} \ (\text{mk}f_2 \ (\text{mk}f_1 \ f)) \ (\text{mk}z_2 \ (\text{mk}z_1 \ z)) \ x\]
\[= \text{foldr} \ ((\text{mk}f_2 \circ \text{mk}f_1) \ f) \ ((\text{mk}z_2 \circ \text{mk}z_1) \ z) \ x\]
\[= \text{foldr} \ f \ z \ (\text{build} \text{fold} \ (\text{mk}f_2 \circ \text{mk}f_1) \ (\text{mk}z_2 \circ \text{mk}z_1) \ x)\]

which establishes our result:

\[\text{build} \text{fold} \text{mk}f_1 \text{mk}z_1 \ (\text{build} \text{fold} \text{mk}f_2 \text{mk}z_2) = \text{build} \text{fold} \ (\text{mk}f_2 \circ \text{mk}f_1) \ (\text{mk}z_2 \circ \text{mk}z_1)\]

While this gives us confidence that Deforestation is a possible optimization, we have already seen that referential transparency [56], and therefore equational reasoning, does not always apply in Curry. We need to show that both expressions will evaluate to the same set of values in any contest. In fact, as they are currently stated, These theorems do not actually hold for Curry. However, with a few
assumptions, we can remedy this problem. First, we need to rewrite our rules so that the reduced expression is in A-Normal form.

\[
\text{build\_fold \ mkf \ mkz} \ (\text{build} \ g) = \text{let} \ g' = (\lambda c \ n \rightarrow \text{let} \ f = \text{mkf} \ c \\
\hspace{2cm} z = \text{mkz} \ n \\
\hspace{2cm} \text{in} \ g \ f \ z) \\
\hspace{2cm} \text{in} \ \text{build} \ g'
\]

\[
\text{foldr} \ f \ z \ (\text{build\_fold \ mkf \ mkz} \ xs) = \text{let} \ f' = \text{mkf} \ f \\
\hspace{2cm} z' = \text{mkz} \ z \\
\hspace{2cm} \text{in} \ \text{foldr} \ f' \ z' \ xs
\]

\[
\text{build\_fold \ mkf\_1 \ mkz\_1} \ (\text{build\_fold \ mkf\_2 \ mkz\_2} \ xs) = \text{let} \ mkf = \text{mkf\_2} \circ \text{mkf\_1} \\
\hspace{2cm} \text{mkz} = \text{mkz\_2} \circ \text{mkz\_1} \\
\hspace{2cm} \text{in} \ \text{build\_fold \ mkf \ mkz} \ xs
\]

Now we are ready to state our result.

**Theorem 11.** suppose \( f, z, g, \text{mkf}, \) and \( \text{mkz} \) are all FlatCurry functions whose right had side is an expression in A-Normal form, then the following equations are valid.

\[
\text{build\_fold \ mkf \ mkz} \ (\text{build} \ g) = \text{let} \ g' = (\lambda c \ n \rightarrow \text{let} \ f = \text{mkf} \ c \\
\hspace{2cm} z = \text{mkz} \ n \\
\hspace{2cm} \text{in} \ g \ f \ z) \\
\hspace{2cm} \text{in} \ \text{build} \ g'
\]

\[
\text{foldr} \ f \ z \ (\text{build\_fold \ mkf \ mkz} \ xs) = \text{let} \ f' = \text{mkf} \ f \\
\hspace{2cm} z' = \text{mkz} \ z \\
\hspace{2cm} \text{in} \ \text{foldr} \ f' \ z' \ xs
\]

\[
\text{build\_fold \ mkf\_1 \ mkz\_2} \ (\text{build\_fold \ mkf\_2 \ mkz\_2} \ xs) = \text{let} \ mkf = \text{mkf\_2} \circ \text{mkf\_1} \\
\hspace{2cm} \text{mkz} = \text{mkz\_2} \circ \text{mkz\_1} \\
\hspace{2cm} \text{in} \ \text{build\_fold \ mkf \ mkz} \ xs
\]
**Proof.** We show the result for foldr-build, and the rest are similar calculations. We intend to show that for any \( f, z, \) and \( g \) that the following equation holds.

\[
\text{foldr } f \ z \ (\text{build } g \ (\cdot \ [])) = g \ f \ z
\]

That is, we show that \( \text{fold } f \ z \ (\text{build } g \ (\cdot \ [])) \) reduces to the same values as \( g \ f \ z \).

We proceed in a manner similar to [31]. First, notice that \( \text{build } g \ (\cdot \ []) \) is constructing a list. However, since \( g \) is potentially non-deterministic, and it might fail, we may have a non-deterministic alternation of lists when evaluating this expression. After evaluating \( \text{build } g \ (\cdot \ []) \) we will produce an alternation of several lists.

\[
\text{build } g \ (\cdot \ []) = g_{1,1} : g_{1,2} : g_{1,3} : \ldots \text{end}_1
\]

\[
\ ? g_{2,1} : g_{2,2} : g_{2,3} : \ldots \text{end}_2
\]

\[
\ldots
\]

\[
\ ? g_{k,1} : g_{k,2} : g_{k,3} : \ldots \text{end}_k
\]

Where, for all \( i, \text{end}_i = [] \ ? \bot \).

Here we have a alternation of \( k \) lists, and each list ends either with the empty list, or the computation may have failed along the way. Therefore, \( \text{end}_i \) may be either \([\] \) or \( \bot \). In fact, it might be the case that an entire list is \( \bot \), but this is fine, because that would still fit this form defined above. We can generalize this by passing arbitrary arguments to build. The expression \( \text{build } g \oplus z \) evaluates to the following alternation of values.

\[
\text{build } g \oplus z
\]

\[
= (g_{1,1} \oplus g_{1,2} \oplus g_{1,3} \oplus \ldots \text{zend}_1) \ ?
\]

\[
(g_{2,1} \oplus g_{2,2} \oplus g_{2,3} \oplus \ldots \text{zend}_2) \ ?
\]

\[
\ldots
\]

\[
(g_{k,1} \oplus g_{k,2} \oplus g_{k,3} \oplus \ldots \text{zend}_k)
\]

Where, for all \( i, \text{zend}_i \) is \( \bot \) if \( \text{end}_i \) is \( \bot \) and \( z \) otherwise.
Now, let us see what happens when we normalize the entire expression. Recall that if $f$ is a dominator of $a \oplus b$, then $f(a \oplus b) = f(a) \oplus f(b)$ [9]. Therefore if all arguments are in A-Normal form, then function application distributes over choice. Since $\text{foldr}$ is a dominator of everything in $\text{foldr} \oplus z(\text{build } g (:)[])$ we have the following derivation.

$$
\text{foldr} \oplus z(\text{build } g (:)[])
= \text{let } \text{fold} = \text{foldr} \oplus z \\
\text{in } \text{fold}(\text{build } g (:)[])
= \text{let } \text{fold} = \text{foldr} \oplus z \\
\text{in } \text{fold}(g_{1,1} : g_{1,2} : \ldots : \text{end}_1) \\
\text{fold}(g_{2,1} : g_{2,2} : \ldots : \text{end}_2) \\
\ldots \\
\text{fold}(g_{k,1} : g_{k,2} : \ldots : \text{end}_k)
= (g_{1,1} \oplus g_{1,2} \oplus g_{1,3} \oplus \ldots \text{z}_{\text{end}_1}) \\
(g_{2,1} \oplus g_{2,2} \oplus g_{2,3} \oplus \ldots \text{z}_{\text{end}_2}) \\
\ldots \\
(g_{k,1} \oplus g_{k,2} \oplus g_{k,3} \oplus \ldots \text{z}_{\text{end}_k})
= g \oplus z
$$

Where, for all $i$, $z_{\text{end}_i}$ is $\perp$ if $\text{end}_i$ is $\perp$ and $z$ otherwise. This proves the result.

$\square$

Note that while this does prove the result, there are still some interesting points
here. First, we never made any assumptions about \( f \) or \( z \). In fact, we did not really make any assumptions about \( g \), but we did at least give an explicit form for its values. This form is guaranteed by the type. This line of reasoning looks like a promising direction for future explorations into parametricity for functional-logic programming.

Second, it should be noted that branches in \( g \) that produce \( \bot \) do not necessarily fail when evaluated. If \( f \) is strict, then any failure in the list will cause the entire branch to fail. Consider the following expression:

\[
\text{foldr} \ (\lambda x \ y \rightarrow 1) \ 0 \ (\text{build} \ (\lambda c \ n \rightarrow 0 \ 'c' \ 1 \ 'c' \ \bot))
\]

Evaluating the expression rooted by \( \text{build} \) to constructor normal form would produce a failure, since the tail of the list is \( \bot \). However, since the first parameter in the expression rooted by \( \text{foldr} \) never looks at either of it is arguments, this branch of the computation can still return a result.

In this chapter we have developed three optimizations to help reduce the memory allocated by Curry programs. These optimizations seem effective, and we have shown why they are correct, but we still need to find out how effective they are. In the next chapter we show how well our compiler compares to Pakcs, Kics2, and MCC on the benchmarking suite provided by Kics2. We also show the results for each optimization individually, and then combined.
Now that we have finally implemented all of the optimizations, we need to see if they were actually effective. Before we can look at the results, we need to discuss methodology. The test suite is based on the test suite from the Kics2 compiler \([28]\). We have removed some tests, and added others in order to test specific properties of our compiler.

Specifically, we removed all of the tests that evaluated the functional pattern operator $=:<=$. since this is an extension of Curry. While the \texttt{RICE} compiler does support this operation, it was not a focus of this work, and we have not tested it enough to be confident in its implementation.

Furthermore, we added a few tests to demonstrate the effectiveness of deforestation. The benchmark suite for Kics2 contained very few examples of code with multiple list operations.

In order to characterize the effectiveness of our optimizations, we are interested in two measurements. First, we want to show that the execution time of the programs is improved. Second, we want to show that optimized programs consume less memory. The second goal is very easy to achieve. We simply augment the run-time system with a counter that we increment every time we allocate memory. When the program is finished running, we simply print out the number of memory allocations.

Execution time turns out to be much more difficult to measure. There are many factors which can affect the execution time of a program. To help alleviate these problems, we took the approach outlined by Mytkowicz et al. \([83]\). All programs
were run multiple times, and compiled in multiple environments for each compiler. We took the lowest execution time. We believe these results are as unbiased as we can hope for; however, it is important to remember that our results may vary across machines and environments. For most of our results the RICE compiler is a clear winner.

9.1 TESTS

Our test suite is based on the Kics2 test suite [28]. We split the functions into three groups: Numeric computations meant to test Unboxing; non-deterministic computations; and list computations meant to test Deforestation. We do not have any specific tests for shortcutting, because it applies in almost every program.

- **Numeric computations:**
  - **fib** is the Fibonacci program from Chapter 6.3.
  - **fibNondet** This is the same program, but we call it with a non-deterministic argument.
  - **tak** computes a long, mutually recursive, function with many numeric calculations.

- **Non-deterministic computations:**
  - **cent** attempts to find all expressions containing the numbers 1 to 5 that evaluate to 100.
  - **half** computes half of a number defined using piano arithmetic by trial and error starting from 0.

  \[
  \text{half } n \mid x + x == n = x
  \]

  where $x$ free
- **ndTest** computes a variant of *fib* that non-deterministically returns many results.

$$fib\ n$$

\[ \begin{align*}
  &| n < 2 = 0 \ ? 1 \\
  | otherwise = fib\ (n - 1) + fib\ (n - 2)
\end{align*} \]

- **perm** computes all of the permutations of a list by computing a single permutation non-deterministically.

- **queensPerm** Computes solutions to the n-queens problem by permuting a list, and checking if it is a valid solution.

- **primesort** non-deterministically sorts a list of very large prime numbers.

- **sort** sorts a list by finding a sorted permutation.

- **last** A program to compute the last element in a list using free variables.

- **schedule** The scheduling program from the introduction.

- **Deforestation:**

  - **queensDet** computes solutions to the n-queens problem using a backtracking solution and list comprehension.

  - **reverseBuiltin** reverses a list without using functions or data types defined in the standard Prelude.

  - **reverseFoldr** reverses a list using a reverse function written as a fold.

  - **reversePrim** reverses a list using the built-in reverse function and primitive numbers.

  - **sumSquares** computes \( \text{sum} \circ \text{map square} \circ \text{filter odd} \circ \text{enumFromTo} 1 \).

  - **buildFold** computes a long chain of list processing functions.
– **primes** computes a list of primes.

– **sumPrimes** computes \textit{sumPrimes} from Chapter 5.

The results of running the tests are given in Figure 9.2 for timing, and 9.3 for memory. All times are normalized. In Figure 9.1 the times are normalized to \textsc{Rice}, and in Figure 9.2 all results normalized to the unoptimized version in order to see the improvement of optimizations. Memory results are measured in the number of allocations of nodes. We also include a comparison all of 3 prominent Curry compilers, Pakcs, Kics2, and Mcc, against \textsc{Rice} in Figure 9.1. We optimized these compilers as much as possible to get the best results. For example Kics2 executed much quicker when run in the primitive depth first search mode. We increased the input size for tak, buildFold, and sumPrimes in order to get a better comparison with these compilers. However, we were not able to run the buildFold test, or the reverseBuiltin test, for the Pakcs compiler. They were both killed by the Operating System before they could complete. We timed every program with Kics2 \cite{28}, Pakcs \cite{38}, and the Mcc \cite{78} compiler. Unfortunately we were not able to get an accurate result on how much memory any of these compilers allocated, so we were unable to compare our memory results.

We also show how our compiler compares against \textsc{GHC} in Figure 9.4. Since most examples include non-determinism or free variables, we are unable to run those. We run our optimized code against unoptimized \textsc{GHC} and optimized \textsc{GHC}.

There are a lot of interesting results in tables 9.1, 9.2, and 9.3 that we feel are worth pointing out. First, it should be noted that the Mcc compiler performed very well, not only against both Kics2 and Pakcs, but it also performed well against \textsc{Rice}. In most examples it was competitive with the unoptimized code, and ahead of it in several tests. It even outperformed the optimized version in the cent example. We are currently unsure of why this happened, but we have two theories. First, the code generation and run-time system of Mcc may just be more efficient than

Table 9.3: Results for amount of memory consumed while running programs compiled at each optimization level.
Table 9.4: Comparison of RICE and GHC on deterministic programs.

RICE. While we worked to make the run-time system as efficient as possible, it was not the focus of this compiler. Mcc also translated the code to Continuation Passing Style [22] before generating target code. This may be responsible for the faster execution times. Our other theory is that Mcc supports an older version of Curry that does not include type classes. Mcc may have performed better simply by not having to deal with that overhead.

Aside from the surprising performance of Mcc, we found a couple of results in our optimizations that surprised us as well. First, the half program used more memory with basic optimizations turned on then it did with no optimizations. This is because strictness analysis created a worker function, but it was not able to cancel out any of the new Int constructors. While this did cause memory usage to go up a little, it did not effect the execution time. However, we could disable strictness analysis unless unboxing is turned on. Second, the ndtest used a bit (about 0.05%) more memory with the unboxing optimization. This is because of a confluence of two side effects of the optimization. Without unboxing we can not determine that the parameters to primitive operations are needed, so we can not force evaluation. This means that instead of evaluating each piece
of the Fibonacci function separately, we need to construct the entire contractum \( \text{fib} (n - 1) + \text{fib} (n - 2) \) and evaluate it. Because of this, the optimized code only contains a single case expression. The other factor is our solution to the non-determinism problem from section 3.2.3. Since we are returning several results, and the unboxed \( \text{fib} \) function contains several cases, we have to push more case functions onto the backtracking stack. While this does allocate a little more memory, we believe that the 2x speed-up in execution time is worth the sacrifice.

In terms of effectiveness, unboxing seemed to be the clear winner. Deforestation did not seem to be nearly as effective, but we believe this is more related to the test suite than anything else. These are all small programs that do not include many list processing operations. We believe that, on larger programs, deforestation would have more opportunities to fire. Shortcutting typically performed well, and compensated for the lack of unboxing in several situations. We think the most interesting part of these results is the effect of combining these optimizations. In particular, unboxing and shortcutting work very well together, often reducing the amount of memory consumed more than either optimization alone. This can be seen in Perm, there node of the optimizations seemed to help, but combining all of them produced a significant speedup.

Generally \texttt{RICE} compares very favorably with all of the current compilers, only losing out to Mcc on the cent example. We focus on the Kics2 compiler, because that was the best performing compiler that is still in active development. With this comparison \texttt{RICE} performs very well, showing anywhere form a 2x to 50x execution speed-up on all of the non-deterministic programs, and a 3x to 50x improvement on the deterministic programs. Even comparing against Mcc, we typically see a 2x speed-up. The only excepts are cent, and programs that cannot be optimized, such as perm. We also see a very impressive speedup on \texttt{fibNondet} compared to Kics2. However, this is a known issue with the evaluation of non-deterministic expressions with functions with non-linear rules. We do believe that this is important to note,
because these programs are common in Curry, and is the reason that we could not use Kics2 to develop RICE.

This is a very impressive speed-up, but we have already discussed the reason for it. After we applied Unboxing and Shortcutting, we were able eliminate all but a constant number of heap allocations from the program. This would be a great result on its own, but it gets even better when we compare it to GHC. Compiling the same fib algorithm on GHC produced code that ran about three times as fast as our optimized RICE code, and when we turned off Optimizations for GHC we ran faster by a factor of 8. It is not surprising to us that our code ran slower than GHC. The run time system is likely much faster than ours, and there are several optimization in GHC that we have not implemented. In fact, we would be shocked if it managed to keep up. What is surprising, and encouraging, is that we were competitive at all. It suggests that Curry is not inherently slower than Haskell. We believe that a more mature Curry compiler could run as fast as GHC for deterministic functions. This would give us the benefits of Curry, such as non-determinism and free variables, without sacrificing the speed of modern functional languages.

In this chapter we have justified the benefit of these optimizations to Curry. In the next chapter we look at possible future directions to take this work, and we conclude.
These results were honestly significantly better than we ever expected with this project. Initially, we hoped to compete with Kics2, since it was leveraging GHC’s optimizer to produce efficient code. However, we found that could we beat Kics2 in all cases, and in some cases the results were simply incomparable. In some cases we were even able to compete with GHC itself. Furthermore, we have shown that the memory optimizations really were effective for Curry programs. This is not much of a surprise. Allocating less memory is a good strategy for improving run-time performance. It is good to know that the presence of non-determinism does not affect this commonly held belief.

It is a little more surprising that these optimizations all turned out to be valid in Curry. In fact, a surprising number of optimizations are valid in Curry under suitable conditions. This might not seem very significant until we look at what optimizations are not valid. For example, common sub-expression elimination was not included in this compiler, because it simply is not a valid Curry transformation. It introduces sharing where none existed. If the common sub-expression is non-deterministic, then we will change the set of results. On the other hand, common sub-expression elimination is fairly innocuous in most other languages.

10.1 CONTRIBUTIONS

In this dissertation we built an efficient implementation of the Curry language. We discussed the evaluation and run-time system for our implementation, and showed
that we can fix some of the inefficiencies in Pakcs and Kics2 with case functions and fast backtracking. We justified these changes with the path compression theorem.

We introduced the **GAS** system for easily constructing program transformations in Curry. Then we showed that, after converting programs to A-Normal Form, many optimizations still remain valid. Specifically, we showed that both inlining and reduction remain valid for Curry programs, which is not true in general.

We then showed 3 memory optimizations that have not been implemented for functional logic programs. For the first optimization, we implemented unboxing via [91], and justified its correctness. For the second optimization, we showed a new optimization for functional logic programs called case shortcutting. We showed the problems with trying to elide constructing a node that is evaluated in a case expression, then we showed how this problem can be solved with a new node. For the final optimization, we implemented shortcut deforestation [46], and showed that, under suitable conditions, it remains correct for functional logic programs. In order to get decent performance out of this optimization, we developed a scheme for outlining partial applications, and optimizing them.

Finally, we showed that using an optimizing compiler, we can improve the speed of Curry programs significantly. With our optimizations, programs ran anywhere from 10 to 1000 times faster than Kics2, which is the current state of the art. We also saw that programs compiled with optimizations are almost always at least twice as fast as those compiled without, and sometimes up to twenty times as fast.

### 10.2 FUTURE WORK

Most curries are made from curry powder and coconut milk, however our Curry was mostly made from low hanging fruit. As nice as our results are, we would like to see this work extended in the future. We believe that a better inliner and strictness analyzer would go a long way to producing even more efficient code.

In fact, a general theory of inlining in Curry would be hugely beneficial. One
of the biggest drawbacks to this compiler is that we can not represent lambda expressions in FlatCurry, and inline them. Before we could even attempt this, we would need to know when it is safe to inline a lambda in Curry.

We would also like to move from short-cut Deforestation to Stream Fusion. This should be possible, but it would require a more sophisticated strictness analyzer, and we may not be able to get away with our combinator approach.

We would also like to see the development of new, Curry specific, optimizations. Right now the ? operator acts as a hard barrier. We can move let-bound variables outside of it, but we can not move the choice itself. However, there may be an option for using pull-tabbing or bubbling to move the choice to make room for more optimizations.

For personal reasons we would also like to bootstrap RICE with itself. This would significantly decrease the time it takes to compile large Curry programs. Right now, RICE is compiled using Pakcs. Currently Kics2 is not a feasible option for compiling RICE, because of performance issues with non-deterministic function. So, compiling RICE in itself would significantly improve the performance of the compiler. There are still several hurdles to overcome before this can be achieved. First, we would need an implementation of either the FindAll library or the SetFunctions library. Both of these libraries rely on external functions that aren’t a part of standard Curry, and would need to be implemented.

We would also like to move from C to LLVM. This would allow for more optimizations including Tail Call Optimization. We currently are limited by the recursion depth of the machine, and TCO could allow us to compile more programs. Moving to LLVM would also greatly help in the development of a garbage collector. Initially LLVM was rejected because we were more familiar with C.

Finally, developing a better run-time system would also be an important improvement. While we did work to make sure our run time system was efficient, it could certainly be better. Integrating this work with the Sprite compiler.
might solve this issue.

10.3 CONCLUSION AND RELATED WORK

We have presented the RICE Optimizing Curry compiler. The compiler was primarily built to test the effectiveness of various optimizations on Curry programs. While testing these optimizations, we have also built an efficient evaluation method for backtracking Curry programs, as well as a general system for describing and implementing optimizations. The compiler itself is written in Curry.

This system incorporated a lot of work from the functional language community, and the Haskell community in particular. The work on general optimizations [65], Inlining [64], Unboxing [91], Deforestation [46], and the STG-machine [60,63] were all instrumental in the creation of this compiler, as well as the work by Appel and Peyton-Jones about functional compiler construction [21,22,59].

While there has been some work on optimizations for functional-logic programs, there does not seem to be a general theory of optimization. Peemöller and Ramos et al. [87,89] have developed a theory of partial evaluation for Curry programs, and Moreno [80] has worked on the Fold/Unfold transformation from Logic programming. We hope that our work can help bridge the gap to traditional compiler optimizations.

The implementation of the GAS system was instrumental in developing optimizations for this compiler. It not only allowed us to implement optimizations more efficiently, but also to test new optimizations, and through optimization derivations, discover which optimizations were effective, which were never used, and which were wrong. This greatly simplified debugging optimizations, but it also allowed us to test more complicated optimizations. Often we would just try an idea to see what code it produced, and if it fired in unintended places. It is difficult to overstate just how useful this system was in the compiler.

While the run-time system was not the primary focus of this dissertation, we
were able to produce some useful results. The path compression theorem, and the resulting improvement to backtracking, is a significant improvement to the current state-of-the-art for backtracking Curry programs.

When starting this project, Shortcutting was already known to be valid for Inductively Sequential Rewrite Systems. It was developed for them specifically, so it is not too surprising that the idea can be translated to Curry programs. However, it was a nice surprise to find that Unboxing and Deforestation were both valid in Curry. It was even more remarkable that, with some simple restrictions, we could make inlining and reduction valid in Curry as well.

We believe that this work is a good start for optimizing Curry compilers, and we would like to see it continue. After having a taste of optimized Curry, we want to turn up the heat, and deliver an even hotter dish. But for now, we have made a tasty Curry with RICE.

[75] S. Libby. Cooking with gas:
making an optimizing curry compiler. 2019.

This document is a guide to the structure of the RICE compiler, and an explanation of the various files. The compiler is split up into 4 sections: the root folder contains code for I/O and a few utility modules; the FlatUtil folder contains convenience functions for FlatCurry programs, as well as the implementation of the GAS system; the Optimizations folder contains code for transforming FlatCurry into a canonical form and optimizing FlatCurry; and the Compile folder contains modules used for code generation, which include the transformation to ICurry as well as the C code generator.

A.1 THE RICE COMPILER

The first section is the root of the project. Here we have 4 notable files: Main.curry, which is responsible for parsing arguments, and general control flow; File.curry, which is responsible for reading files, and getting absolute paths to directories; Util.curry, which contains some general utility functions; and Graph.curry, which is an implementation of “Structuring Depth-First Search Algorithms in Haskell”.

A.1.1 Main.curry and I/O

This file dictates the general flow of the compiler. The compiler has a few command line arguments, and can be run in two different modes. If the -g argument is passed, then the compiler will assume that the program has already been optimized, and that ICurry has been generated. It will only attempt to generate C code. This
mode is useful for testing changes to the code generator. Any other changes really need the full optimization of the code.

The arguments are defined below. The format is flag, longName, description.

A.1.2 File.curry

File has a number of useful utility functions for manipulating FlatCurry/ICurry/C files. The most important of these is readFlatCurryWithImports. This function performs a topological sort on the files based on their imports, and returns a list of FlatCurry.Prog objects in topological order. It also marks each file with whether or not the file has already been compiled and optimized. This prevents us from recompiling files. This file also contains functions to determine the absolute paths for the FlatCurry, optimized FlatCurry, ICurry, C, and H files for each program.

A.1.3 Util.curry

This file contains several useful utilities including instances of Functor for both IO, and Maybe, as well as fork, mapFst and mapSnd from the Haskell Arrow library.

It also contains the definitions for the sorted list combinators. These functions perform set union, set difference, and set intersection.

\[ (+ + -), (\setminus -), (\&\& -) \]
For the implementation we assume the set is a sorted list. So, we can do union and intersection cheaply by just maintaining the sorting. This is not useful if you want to look something up in a set, but it gives you $O(n)$ time construction of the set of variables in an expression.

This is also the implementation of the State and ReWriter Monad. State follows the usual construction. Any efficiency improvement here would be beneficial for the whole compiler. ReWriter is effectively StateT Writer. It is used in the GAS system, so any efficiency improvements have a pervasive effect on performance.

We also include a wrapper for computing strongly connected components, since that operation comes up a lot.

### A.1.4 Graph.curry

This module contains a lot of useful Graph Theory utilities. The ideas are lifted directly from “Structuring Depth-First Search Algorithms in Haskell”.

### A.2 THE GAS SYSTEM

The GAS system is really the heart of this compiler. The idea is described in Chapter 4. The FlatUtils folder contains two files related to GAS. First The FlatUtils.Curry file contains several utility functions for working with FlatCurry programs. Next, Gas.Curry contains the implementation of the GAS system.

#### A.2.1 FlatUtil.curry

FlatUtils contains a number of functions to get general information about FlatCurry expressions. It also includes functions for constructing and applying substitutions. We represent a substitution as a function from \(\text{VarIndex}\) to \(\text{Expr}\). We can construct a substitution with an identity function \(\lambda x \rightarrow \text{Var } x\). This is the purpose
of \textit{idSub}. We can add a new variable to a substitution with the \texttt{@>} combinator, as shown by the \((x, e) @> s\). This will extend the substitution \(s\) with \(\{x \mapsto e\}\).

We can apply a substitution with the \textit{sub} function. A renaming is a special substitution where we just change the names of variables. We can do this with the \textit{rename} function. Finally, we define functions for getting the type and constructor name for primitive types.

\subsection*{A.2.2 \texttt{Gas.curry}}

The \texttt{GAS} library is built around the idea of an optimization. For our compiler, an optimization is a function of type \((\texttt{Int, Bool}) \rightarrow \texttt{Expr} \rightarrow (\texttt{Expr}, \texttt{String}, \texttt{VarIndex})\).

We provide each optimization with the next fresh variable, and whether or not optimization is being applied to the root of the function. We return the transformed expression, the name of the optimization that was applied, and the number of new variables that were created.

The two functions that the user can call are \textit{simplify} and \textit{showWork}. \textit{simplify} will run the optimization until it no longer applies, and return the resulting expression. \textit{showWork} will run the optimization while it can, but it will also build up an optimization derivation. It returns the transformed expression, the optimization derivation as a \texttt{String}, and the number of optimizations that it was able to apply. Both of these functions allow the user to pass in a maximum number of optimizations to apply. The \textit{run} function does the real work of optimizing, and it is described in Chapter 4.

We also include \textit{loop} and \textit{loopIO} functions for applying a transformation at the function level. This is useful for transformations that need to create new functions. An example of this is moving a case inside of a let expression into its own function.

Finally, we include a few functions for quickly building up common FlatCurry expressions. These include function composition, apply nodes, and partial applications. We also include FlatCurry definitions for \textit{build} and \textit{foldr}, which are
functions discussed in chapter 7.

A.3 OPTIMIZATION

The optimization folder is, unsurprisingly, the largest folder. Several modules are small, but they all serve a unique purpose. The files are ordered by the use in the optimization pipeline.

DataTable.curry provides functions for constructing and inspecting a table of data type definitions. FunTable.curry is similar. Optimize.curry contains the control flow code for managing the entire optimization process. Preprocess.curry manages the code for converting FlatCurry programs into canonical form. ANF.curry contains the code for transforming into Administrative Normal Form. Ordering.curry contains code for sorting the functions into an optimal ordering for optimization. Strictness.curry contains code for performing strictness analysis. Primitives.curry contains optimizations for primitive values, such as constant folding. Inline.curry contains optimizations for inlining, reduction, and dead code elimination. Postprocess.curry contains code to clean up functions after optimizations, and move let bound cases out into their own functions.

A.3.1 Flags.curry

This is a simple file to set which optimizations are run. This was designed for testing different optimizations, and will be moved into the compiler flags at some point.

A.3.2 DataTable.curry

A DataTable is a bidirectional mapping from Data Types to Data Constructors. This is stored as a pair of tables $tmap$ and $cmap$. The $tmap$ table takes a type, and returns the list of all constructors for that type, and the $cmap$ table takes a
constructor name, and returns the type returned by constructor. This is primarily used by the Case Fill transformation, but it is also used in the code generator.

A.3.3 FunTable.curry

The Function Table contains a number of useful properties about functions, which are described in chapter 6. Specifically, we can query the following: nondet, is the function possibly non-deterministic; loopbreaker, was the function marked as a loopbreaker while ordering the functions; arity, what is the arity of the function; params, what are the parameter names; freshVar, what is the next fresh variable name; bodySize, how large is the syntax tree for the function; inlinable, do we consider the function a good candidate for inlining? There are also two composite queries we can make: simple, is the function trivially inlinable; cancels, is the function likely to cause case canceling if we inline it?

A.3.4 Optimize.curry

Optimize.curry handles the control flow for optimizations. There are two modes that a program can be optimized in. The optimize function will transform a FlatCurry program into canonical form, and run optimizations on it. The optimizeT function will do the same thing, but it also produces output. The optimize function has trouble completing with longer functions. We suspect that this is a problem with laziness, but it is hard to pin down.

A.3.5 Preprocess.curry

This module contains several transformations to put a FlatCurry function into canonical form. Specifically, it contains Let Float, Case in Case, Double Apply, Case Apply, Blocks, Alias, Case Var, Fix Partial, and Unapply from chapter 5. It also contains the String Const transformation for transforming literal strings into string constants which take less memory at run-time.
A.3.6 ANF.curry

This file contains code to put a canonical FlatCurry expression into A-Normal Form. The transformation almost directly mirrors “The Essence of Compiling with Continuations” [41].

A.3.7 Ordering.curry

This file contains code for ordering a list of functions based on their call graph. Ideally we would topologically sort the call graph, and process the list in reverse order. However, the call graph may not be acyclic. To deal with this possibility we compute the strongly connected components, then we score each function in a component based on how useful we think it would be to inline that function. We take the least useful function, and mark it as a loop breaker. Then we remove it from the graph, and compute the strongly connected components again. We repeat this process until we are left with a DAG, which we can process in topological order. All loop breakers are processed at the end since they cannot be inlined.

A.3.8 Strictness.curry

This file runs a simple strictness analysis on FlatCurry functions. This analysis is simple abstract interpretation, and it builds a StrictTable. Which is just a mapping from function names to the variables that we are sure are strict. We also include the splitWorker function which will attempt to apply the wrapper/worker split to any function that has a strict parameter and is recursive.

A.3.9 Primitives.curry

This file contains the code for the Prim Cond optimization for replacing boolean case expressions with pcase, as well as the code for constant folding.
A.3.10 Inline.curry

This file contains the majority of the optimizations. Specifically, it includes the following: **Inline Literal** which will inline `let v = l in e` where `l` is a literal; **Inline Constructor** which will inline `let v = C vs in e`; **Inline Case** which will inline `let v = case x of bs1 in case v fo bs2`; **Inline fold/build** and variants inline the `build` and `build_fold` functions; **Let Folding** which moves let bound variables closer to where they are used; **Case Canceling** which is described in chapter 6; **Reduce Base** for if the reducible function is at the root of the expression; **Reduce Useful** for if we think that reducing the expression will lead to more optimizations; **Reduce Simple** for if the body of the reducible function is small; **Reduce Cancels** for if reducing this function will lead to more case canceling; **Reduce Let** for if the reducible function is not a let bound variable, but the result of a let expression; **Reduce branch** for if the reducible function is in the branch of a case; **Dead Code Elimination** removes unused variables and trivial expression like `let in e`; **Fold/Build** and variants perform the shortcut deforestation optimization described in chapter 7; and **Case Folding** which applies the following transformation.

\[
\text{CaseFolding}
\]

\[
\text{let } t = \text{case } e \text{ of } \\
C1 \; x \rightarrow \; e1 \\
C2 \; y \rightarrow \; e2 \\
\text{in case } e \text{ of } \\
C1 \; a \rightarrow \; e11 \\
C2 \; b \rightarrow \; e22 \\
\Rightarrow \\
\text{case } e \text{ of } \\
C1 \; a \rightarrow \; \text{let } t1 = e1 \ [x \rightarrow a] \ e11 \ [t \rightarrow t1] \\
\]
\[
C2 \ b \to \text{let } t2 = e2 \ [y \to b] \ e22 \ [t \to t2]
\]

This seems like it would not be useful, but it actually crops up several times because of inlining functions defined in typeclasses.

A.3.11 Postprocess.curry

This file is responsible for a few areas of cleanup. First, we attempt to outline any large partial applications. The goal here is that when we create a new function for partial application, we can optimize it. If we fail to find any optimizations, we ignore that outline. Otherwise, we replace the partial application with a call to the outlined function. Next, we move any let bound variable defined with a case into its own function. Then we fix any partial applications that might have changed due to outlining, convert every function to a more strict version ANF, look for any aliasing problems, and mark all case expressions where case shortcutting from chapter 7 can apply. Finally, we rename all of the variables in a function so they are consecutive integers.

A.4 CODE GENERATION

The final component of the compiler is the code generator. This includes both the translation from FlatCurry to ICurry, and the generation of C code. Due to the size of the files generated, we don’t construct the .c or .h files as a single string. Instead, we pass in a file writer object, and continuously append to the files.

A.4.1 IUtil.curry

IUtil.curry is a library of utility function for working with ICurry. It is similar to the FlatUtil.curry library, but not as full featured.
A.4.2 ToICurry.Curry

ToICurry.curry contains the code for translating from FlatCurry to ICurry. The process is described in chapter 3. The algorithm follows that chapter pretty closely, but we do add a case for translating the \texttt{pcase} construct.

A.4.3 C.curry

C.curry is a library for constructing C code. Instead of constructing an AST of a C program, and writing a pretty printer, we opted to write functions that produce formatted C strings. This works very well in practice, and is similar to creating an EDSL. As an example, we may write code like the following:

\begin{verbatim}
cIfElse (x ! = 2)
 |
     scall "function1" [x, 2]
 |
     |
     scall "function2" [x, 3]
 |
\end{verbatim}

to generate the code
\begin{verbatim}
if(x != 2)
{
    function1(x,2);
}

else
{
    function2(x,3);
}
\end{verbatim}

There are several small functions and operations which should not be too difficult to understand, but some of the more useful ones include:
call and scall which produce an expression and statement function call respectively; cblock which contains a block of C code; cIf, cElse, cIfElse, cWhile, cSwitch, and cCase which all generate control flow statements; cFunDefn, cFunDecl for declaring and defining function; hFunDefn for defining functions in a header file; and several others. We also include several functions that define C code that is specific to our compiler. For example, the nondet function takes a variable x, and returns \( x.n\rightarrow\text{nondet} \). While this is not a piece of general C syntax, it is an expression we need to generate frequently.

### A.4.4 PrimOps.curry

This file contain a table of functions for generating code to handle primitive operations. There are two functions for each primitive, a set function and a make function. Both of these are described in chapter 5.

### A.4.5 ToH.curry

This file contains the code for generating Header files. Each header file is broken up into several sections. We \#include\ the relevant files, generate a unique tag for every constructor in a type that is declared in the module, generate the symbols for each constructor and function, check for any constructors with no arguments and declare them as constants as described in chapter 5, declare the set functions for data constructors and functions, declare the make functions for data constructors and functions, and declare the set/make functions for free variables of each type.

### A.4.6 ToC.curry

This file handles the majority of the work of code generation. Theoretically, it is a straightforward syntax directed translation, but there are a few more complexities. The funSource function generates the source code for each ICurry function. It is split into 3 parts. First funSource_base generates the source code for the function.
Then `funSource_case` generates a separate function for each case statement in the ICurry program. This is described in chapter 3 as a technique to handle non-determinism without having to flatten every function to a single case statement. Finally, the `funSource_RET` handles the generation of the RET functions described in the case shortcutting optimization in chapter 7. If any case expression is marked for case shortcutting (with a negative variable) then we normalize the scrutinee for that case using the global RET node. We call the RET hnf function, which is responsible for normalizing the expression. It also returns a backup node if the expression in RET was found to be non-deterministic.

In fact, there are a few variables that have a specific meaning in this compiler. Any positive variable is just a normal variable, 0 is the root variable, and -1 represents a primitive case expression. All other negative variables represent expressions placed in the RET node.

The `debug` and `debug_expr` macros are there to help with debugging at runtime. They have 4 different levels, `NONE`, `LOW`, `MID`, and `HIGH`.

The `showIfCase`, `showConsCase`, and `showLitCase` do a majority of the work for generating the code. In particular, `showConsCase` is responsible for generating the loop described in chapter 5. Each case block is handled by a separate function. If the constructor we are reducing to is a primitive constructor, (one of `Int`, `Char`, `Float`) then binding free variables is a little different. Instead of trying to bind the free variable to an `Int` constructor with a free variable inside, we instead take the possible branches in the inner case, and bind our variable to one of those.
